Dr. Esser maintains that the avocado is one of the most valuable foods which nature has given to man and is of special value to vegetarians. It is higher in protein and fat than any other fruit (except nuts). Of course, the fat is more digestible than animal fat. In Guatemala, the avocado is used in place of meat. (Avocados, though botanical, members of the fruit family, are also classified as fat/protein food.)

The principal difference between avocados and nuts is that avocados are about 75% water, and nuts contain only about three to five percent water. Further, all nuts except the almond (and the coconut and chestnut, which are not classified as true nuts) are acid in metabolic reaction, while avocados are alkaline. The diet should predominate in alkaline foods, such as fresh fruits and vegetables—perhaps 80% should be alkaline in reaction. However, the high fat content of the avocado should be a signal that it should not be used excessively. One-half of a medium-sized avocado at a sitting should be adequate, and they should not be used every day.

## **Bananas**

Bananas are available all through the year. It is best to buy them green for ripening at home, where ripening conditions can be controlled. Bananas are usually "gassed" to facilitate ripening. Sometimes it is possible to buy "ungassed" bananas, but it is somewhat doubtful whether they truly have escaped the gassing process. They may have been acquired before having been subjected to "ripening chambers" in this country, but in my understanding that some of the fruit has already been gassed on the vessels carrying them from the tropics.

Bananas, at least, have a good protective skin, so the flesh isn't exposed to chemical sprays. I usually buy the greenest bananas I can find. I put them in a brown paper bag overnight, and expose them to air during the day (on my kitchen counter).

Select bananas free from surface bruises, with skin intact at both tips. Ripen at room temperature. When the skin is bright yellow speckled with brown, the starch will be changed to fruit sugar, and the fruit will be tender, sweet, and easy to digest. Fruit that ripens with brown speckles may not have been gassed, as I have been told that gassed bananas ripen with dark streaks and blotches instead of the brown speckles. I have found that speckled fruit uniformly delightful in taste, so I am inclined to give some credence to this speculation.

Don't buy bananas which are bruised, discolored, or dull and grayish, which means they have been held in cold storage and will never ripen properly. Sometimes bananas that are ripe and ready for eating are sold at reduced prices. We usually are glad to get them, though they must be used that day or the next day. Overripe parts can be cut away; the rest is fine.

We have two stools of banana trees in our yard (in Florida) and harvest small, flavorful bananas some years (when the previous winter's frost has not been too severe).

## **Blackberries, Blueberries, Raspberries, Mulberries, Loganberries, and other small berries**

Peak season June through August. Although they differ in shape or color, these small berries, which often grow wild, are similar in general structure and buying considerations. Freshness and ripeness are prime concerns. Good bright color for the species, plumpness and tenderness, indicate ripeness. Usually, however, the problem is over-ripeness. The berries are also easily mashed. The small containers of berries are expensive and may contain a large percentage of moldy, spoiled berries. If the container is stained or wet, don't buy it. Don't wash the berries until you are ready to use them. They are very fragile and perishable and won't keep long. Ripe raspberries drop their cores, leaving little hollow cups. Blackberries don't. When blackberries are red, they are not ripe.

## **Cactus Fruit (Prickly Pear)**

Fruit season August-September. Available occasionally. Cactus fruit grows on a very large type of cactus. The fruit is smaller than an average sized pear, purplish in color, and covered with small thorns (or spines). The edible, juicy, pulpy fruit is red, and somewhat enjoyable, but not necessarily worth the trouble of dealing with its thorny coat, which makes it difficult to assess its ripeness. I have not seen the thornless variety developed by Luther Burbank. The taste of cactus fruit is slightly tart and it has many fine seeds. It is necessary to cut out the areas with the little spines in order to handle the fruit.

## **Cherimoyas**

This is practically unknown in most U. S. markets, because it is very delicate and does not withstand shipping. I am including it although I have not yet been successful in ever tasting this fruit. Dr. Esser says it surpasses all other fruits, and I encourage you to try it if you ever find it available to you. It is prolific in tropical countries, having originated in Ecuador and Peru, and spreading to Mexico, the West Indies, Africa, India and Polynesia. Weak attempts to cultivate it in some parts of the U.S. have not been particularly successful. This fruit attains its highest perfection on the slopes of the Andes.

The shape of the cherimoya is irregular, sometimes round, sometimes cone-shaped. The skin is delicate, dark green when ripe. The edible part is whitish yellow, juicy and filled with many brown seeds. The taste reminds one of the pineapple, though it is perhaps more delicious and delightfully fragrant.

## **Cherries**

The peak season for this fruit is June and July. Eating cherries appear in May, but one should wait until June for the dark, sweet, flavorful ones, which will also be priced lower by then. Small size cherries are not a good buy; the pit is the same size as in the larger cherries. The most important sign of maturity and sweetness in cherries is a very dark color. They should be bright, glossy and plump and the stems should not look dark and withered. Cherries decay rather quickly, and should be used soon after buying. If you see soft leaking spots or surface mold, don't buy them. Tart cherries are not suitable for eating. Remember that cherries are heavily sprayed and have no tough, peelable skin for protection. Wash them thoroughly and eat sparingly—not every day during the season.

## **Citrus Fruits**

### **Oranges**

Peak season, December through June. Color of the skin is no indication of quality or ripeness. The skin of the first crops of mature oranges in November is green or greenish, but mature oranges are ready for harvest and eating, even when the skin is green. They are, however, not as sweet as oranges harvested a month or so later on. California growers "orange" their green fruit by gassing; Florida shippers put the oranges through a colored wax bath (a "non-toxic" food coloring and wax), because they believe the added color will make the fruit more saleable and the wax will improve the keeping quality. Some fully

ripened fruit even turns green again late in the season. Lucky people who live near orange groves can get uncolored, freshly picked oranges, and, possibly, even organically grown oranges. Organically grown oranges are usually the sweetest.

Organically grown oranges are available if you want to go to the trouble and expense of having them shipped in. See addresses in an earlier part of this lesson.

Firm, heavy oranges are full of juice. Avoid lightweight fruit and very rough surface, which usually signifies a thick skin and a smaller orange. There are many varieties of oranges. In Florida, we get navels, temples, tangelos, valencias, tangerines, and pineapple oranges. There are several varieties of tangerine oranges, including the mandarin, the honey murcott and the satsuma. Tangerines are best when they are a little loose in their skins, but not pulpy around the ends. Tangerines peel very easily, the skin being very loosely connected. Temple and tangelo oranges are also rather easy to peel.

Florida oranges disappear from the market about May, but oranges from California are available all through the year. Several varieties of California oranges are usually available, including navels and valencias. Oranges grown in the United States outside of California, Florida and a small strip of southwest Arizona, must either be very hard varieties, or must have artificial winter protection or heating. Some oranges are thus successfully cultivated in southern Texas, the northern interior of California, and elsewhere. I have received brochures offering shipments of Texas oranges. Jaffa oranges from Israel are sometimes available.

### **Grapefruit**

Peak season, November through April. Grapefruit are really available throughout the year, and are ripe and of consistently good quality, though the price will be higher when they are out of peak season. This is one fruit in which color and blemishes have little relationship to quality, although it is said that rusty looking marks on the skin are an indication of sweetness.

Grapefruit should be firm, thin-skinned and heavy for their size. The smoother the skin, the thinner. A coarse surface and pointed end are signs of thick-skinned, less juicy fruit, but it may still taste good. Wrinkled and rough skin will indicate tough, dry fruit. Skin defects are of no importance, except for large, soft, wet spots. If discolored at the stem end, or if the skin breaks easily, decay has begun. Popular varieties are Marsh, Ruby Red and Duncan. Although the Duncan has many seeds, it is the best in delicious flavor. Indian River (Florida) fruit is considered superior in flavor and quality.

### **Kumquats**

Available in the south in the fall and winter. Some are suitable for eating, some only for making preserves. Some are ovoid, some spherical. A spherical variety native to Florida is very sweet and one can even eat the skin, which is thin, sweet and spongy.

### **Carambolas**

The major crop becomes available in the spring and summer; they are sometimes available in November-December. Available mostly in southern markets. They are usually lemon-colored (unripe) and the clear, watery pulp is too tart and astringent, and they seldom ripen satisfactorily. When orange-colored, they are ripe and pleasantly acid-sweet, with an agreeable flavor. If picked at full maturity, they are good eating.

This fruit is somewhat of a novelty to behold. It has a waxlike surface with deeply ridged sides, and when hanging on the tree, carambolas resemble lanterns. A cross-section or slice of the fruit is star-shaped, since the fruit has an oval, five-angled shape. Carambolas are not citrus fruit, but are acid fruits resembling the citrus in appearance and taste of the flesh.

## **Lemons**

Available throughout the year. Peak season May through July. The habitual use of this strongly acid fruit is not advisable. It can not only cause erosion of the dental enamel, but it tends to retard digestion. Use of lemons in salad dressing is less objectionable than vinegar, but it is better not to use salad dressing at all. Recipes for salad dressings made without vinegar or lemon will be given in Lesson 26. Lemons with a rich, yellow color, reasonably smooth skin and heavy for their size are the best.

## **Limes**

Available year-round, peak season June-July. Comments about lemons also apply to limes.

## **Cranberries**

Peak season, October through December. Cranberries are not recommended for use as food because they contain considerable quantities of malic and benzoic acids. Benzoic acid is a white, crystalline acid used in perfumes, dentrifices and germicides, and to season tobacco. Cranberries cannot be enjoyably used in their natural, raw state unless considerable amounts of sweetening are used, or unless combined with other sweeter fruits, such as oranges. Cranberries are classified as acid fruit, but are best excluded from the diet.

## **Currants**

Not usually available, except in the dried state, or in jellies and jams. Currants grow wild and in gardens in temperate climates. The wild species are small and very sour, but the larger garden varieties have an agreeable acid flavor. The currant resembles a tiny grape, or when dried, a small raisin. There are three varieties, red, white and black. The red variety is richest in mineral content.

## **Dried Fruits**

Available all year. Dried fruits are rich sources of natural sugar, plus all the vitamins and minerals in the fresh fruit. The drying process preserves the fruit by removing about 50% of its water. Almost all of the nutrients remain. Dried fruit is particularly high in iron.

Select only fruit which has been sun-dried, and which does not contain sulfur dioxide or other additives. Fruit which has been dried by artificial dehydration (heat evaporation) is usually dipped into a sulfur dioxide bath to keep it from darkening. Golden raisins, and any dried fruit that is light in color, have been treated with sulfur dioxide. Almost all dried fruit is fumigated during storage or shipping. Dates are usually, pasteurized to prevent molding. Preservatives are not necessary in these products, but some processors add sorbic acid as a preservative, and some add corn syrup or honey to keep them from drying out. Don't buy any dried fruit that contains sorbic acid, sweeteners, or any additives.

## **Dates**

Dates usually only reach us in the dried state. The Calavo and Dromedary brands, available in supermarkets, don't have any additives. The varieties available in health food stores usually don't have any chemicals or sulfur dioxide, but they are sometimes honey-dipped. Some of the popular varieties are Deglet Noor, Medjool, Khadrawi, Barhi, Halawi, Zahidi and Bread dates. Some of the varieties are very large and of superb flavor, but they are seldom available, and quite expensive. I usually buy my organically grown dates from Jaffe Brothers, and "fill in" by purchasing a few at the health food store.

## **Figs**

The two most popular domestic varieties are Calimyrna, the native California variety, which is light in

color and sometimes large and succulent; and Black Mission figs, which are purplish black, with pinkish meat, and are usually small. Calamata strings, imported from Greece, are uncured. Smyrna and Kadota figs are sometimes available. We have a Kadota fig tree on our property, and get a large crop of figs of large size and excellent flavor. We eat figs every day when they are ripening, give large quantities away to friends and neighbors, and freeze the rest, without heating or sweetening. We eat them just barely thawed, and they are not as good as freshly picked raw figs, but they are a welcome addition to our fruit meals in the winter. We buy organically grown dried Calimyrna figs from Jaffe Brothers, and sometimes buy dried figs from the health food store.

## **Raisins**

Sun Maid Thompson seedless raisins (except the "golden"), and Sun Maid muscats, sultanas and currants, are sun-dried without the use of chemicals. S&W raisins (the dark kinds) are also free of sulfur dioxide. Monukka raisins are large choice raisins available in health food stores. I buy my raisins from Jaffe or Covalda or the health food store.

## **Apricots**

Sun-dried, unsulfured apricots are usually very tough and dry and must be soaked overnight to make them palatable. I am very fond of soaked, dried apricots, because they have an excellent flavor and are less sweet than most dried fruit. If dried apricots have an even color and bright, attractive appearance, they have been sulfured.

## **Prunes**

No unsulfured prunes are available in supermarkets, but some are available from Jaffe, Covalda and health food stores. Prunes are high in oxalic acid and their usage should be limited.

Dried Dark Cherries, Dried Bananas, Dried Apples, Dried Peaches and Dried Pears are also available at times. Select only unsulfured fruit.

Dried Litchi Fruit and Dried Carob Pods are also sometimes available. The dried litchi tastes somewhat like the raisin. The shell surrounding it looks like a small brown ball (the shell is red in the fresh state), and the fruit surrounds a large, hard seed. Dried carob pods are hard, stringy, and chewy, but if they are not too dry they have an agreeable taste. The color is dark brown and the dry fruit encloses a number of small, hard, shiny seeds. Carob powder (available at health food stores) is often used as a replacement when a flavor similar to chocolate is desired.

## **Fresh Foods, continued...**

### **Figs (Fresh)**

Peak season, July and August (but rarely available). Figs should be plump and fairly soft, but not mushy, and with no breaks in the skin. The softer they are without being rotten or fermented, the sweeter they will be. If they are fermented, they will smell vinegary. Buy for immediate eating—they are extremely perishable. Figs can be green, yellow, pink, violet, brown or black. In chemical composition, the fig closely resembles that of human milk, especially in regard to the proportion of mineral salts. (See article on figs in this lesson.)

I have found fresh figs for sale about five or six times in my entire life, where I have lived in Indiana and Florida. They may be available more often in other areas of the country. Now that we have our own Kadota fig tree, we enjoy this delicacy regularly; we have one major crop in the spring, and a minor crop in the fall-winter season. We harvest enough to share with friends and neighbors, and put some in our freezer to enjoy during the winter. Our Kadota figs are green until ripe, when they swell, turn yellow and

soften. (See "Dried Fruits" for additional information about figs.)

### **Gooseberries**

Seldom available. The wild varieties are covered with spines, but the large cultivated varieties are completely smooth. American varieties are mostly inferior in size and quality to European species, some of which are almost as large as hen's eggs. Really good ripe gooseberries have a delightful, acid-sweet taste, but I have never found these good gooseberries.

### **Grapes**

Peak season, July through November. The most common varieties are Thompson seedless (early green), Tokay and Cardinal (early bright red), and Emperor (late, deep red). Other varieties are Ribier (dark blue), Red Seedless, Concord, Catawba, Salem, Delaware, Jessica, Muscadine, Malaga, Muscat and Sultana. The first grapes will not be as sweet as those available later. Green grapes are sweetest when the color has a yellowish cast. Red grapes are best when deep red. All grapes should be well-colored, firm and plump, and still attached to the stem. Look for the powdery "bloom." Avoid bunches with small undeveloped berries (they're sour). When the best grapes are available, around early fall, we find Thompson and Red Seedless to be the sweetest and most flavorful, with Ribiers running a close second. Later in the season we have to settle for Emperors, which are usually fairly good. We don't care much for Tokays, but use them occasionally, because they are available late in the season when the other varieties are gone.

Grapes are nutritionally among the best of fruits, but it is too bad that they are so heavily sprayed that they should be eaten sparingly, after thorough washing. You might want to go to the trouble of peeling them, to at least get rid of the worst of the chemicals.

### **Kiwifruit**

Available through the year. The New Zealand kiwifruit is about the size of a hen's egg. It has a thin brown furry skin. Squeeze very gently to check ripeness—it should give a little. The kiwifruit is growing in popularity. If you have never tasted a kiwi, you are in for a treat. When cut in half or sliced, it has a surprising, unusual and attractive appearance—emerald green flesh, with tiny seeds clustered around a light, creamy center. It has a wonderful, delicate, strawberry-like texture and a fresh, tangy flavor all its own. This fruit was formerly known as Chinese Gooseberry. Although most of the kiwis are imported from New Zealand, California is also growing the fruit, with about a thousand acres now in production. The November 1, 1981 Florida Market Bulletin contains a picture of a pair of kiwifruit growing in Florida—it didn't say just where. The article says that, as far as the editor could tell, these were the first pair of kiwifruit to be documented growing in Florida.

### **Litchi Fruit (Fresh)**

Fruit season mid-June—mid-July, seldom available. The fresh litchi (also spelled lichee, lychee, leechee, lichi, laiche) is a grape-like fruit which hangs on the tree in beautiful red clusters, and is luscious when fully ripe. Some of the trees are grown in yards in southern and central Florida. The skin is a thin, leathery shell (hence the name litchi nut, which is often used), purplish-red to bright red when ripe. The flesh is white, similar to the grape, with a sweet taste, jelly-like consistency, and excellent flavor and aroma, surrounding a large hard seed.

### **Loquats**

Peak season January-April, but seldom available in markets. They are grown in yards in southern and central Florida. We have one in our yard which yields a large crop of excellent fruit. The loquat is sometimes called the Japanese Plum, looks more like a small apricot, and tastes slightly acid, or subacid

when totally ripe. Loquats are one to three inches in length, have a pale yellow to orange color and somewhat downy skin. The flesh is also yellow to deep orange in color, and the fruit generally contains three or four seeds. The loquat is very juicy and has an excellent flavor when fully ripe.

## **Mangos**

Peak season, May through August. Mangos can be bought green and ripened at room temperature. It is best to select mangos which are starting to show some signs of ripening, rather than totally hard and green, or totally ripe. Completing the ripening at home under controlled conditions will usually result in better-tasting fruit. The color of the flesh varies from light lemon to deep apricot. In the best varieties, the flesh is smooth and juicy, with an excellent flavor. Such a properly ripened mango, eaten at the peak of its rich, pungent flavor, is delectable. The flavor is somewhat reminiscent of peaches, but much more exotic.

The Haden is a superior variety. The Kent is notable for its smooth texture. In some of the less desirable varieties, the flesh is full of fibers and the flavor unpleasant. The excellent Haden fruit is plump and oval-shaped and often has a rosy blush. When ready to eat, it is yellow and orange, only slightly firm, yielding to gentle pressure. The Haden has a fair amount of fiber, but excellent flavor. The Carrie is a large, green variety of good flavor and texture, and is fiber-free. It turns a paler green and develops dark speckles as it ripens. When ripe enough for full flavor and enjoyment, it is slightly firm, yielding to pressure. Mangos have a tough peel which is a good protective coat against sprays.

## **Melons**

### **Cantaloupe**

Peak season, June through August. Medium to large cantaloupes are usually sweeter and tastier than small ones. Heavy fruit will be juicier, but not necessarily sweeter. Pleasant aroma is the key to ripeness and superior flavor. The melons should yield to pressure, especially at the blossom end. The network of veins in the rind should be thick, coarse and stand out in bold relief, and the rind color should be a yellowish shade, not green. Avoid cantaloupes with smooth spots. If a cantaloupe was not mature when picked, some of the vine stem will adhere to the fruit. In order to be sweet, the mature cantaloupe must be free of the stem, with a smooth, shallow depression where the stem grew. If the melon is mature when picked, it will reach excellent eating quality if ripened at room temperature for a few days.

Don't buy overripe melons, indicated by widespread softening. They will be tasteless and watery. Small bruises are not significant, but large bruises will affect eating quality.

### **Persian Melons**

Peak season, August and September. These melons are a variety of Musk Melon, and look like oversized cantaloupes, but are somewhat rounder with a finer netting. They can be grouped with cantaloupes for selection and use information. As the Persian melon ripens, the dark green rind under the netting turns lighter green and the rind gives under light pressure. Avoid those with dark or greenish black netting. Persians have a dark orange flesh.

### **Casabas**

Peak season, July to November. They are best in September and October. Casabas are not netted like the cantaloupes, nor smooth like the honey dews. Instead, they are profusely marked with longitudinal corrugations. Skin color varies with the variety. Golden Beauty casabas are pointed at the stem end, with green skin that turns to yellow at maturity. They will have a yellow-gold color and a slight springiness at the blossom end when fully ripe. The ripe flesh of a casaba can be either white, yellow or orange in color. Although sweet flavored, the flesh is not as sweet as a honey dew, nor does it have the musky

aroma and flavor of the cantaloupe. Casabas do not "slip" from the vine at maturity; rather they are harvested by cutting the stem when the melons are reasonably mature and held in storage until the blossom end becomes soft. The flesh of an unripe casaba tastes like a cucumber.

### **Crenshaws**

Peak season, August and September, although available July through October. The crenshaw (not cranshaw) is a variety of the casaba. It is a slightly wrinkled, dark green fruit that turns pale yellow-tan at maturity. It has shallow furrows, but the rind is much smoother than that of the Golden Beauty casaba. When fully ripe, it is golden yellow, yields to slight pressure, and has a strong, sweet aroma. The flesh of the ripe crenshaw is a rich orange color, and it has a juicy, rich, rather spicy taste. The crenshaw is large, up to nine pounds, with a rounded blossom end and pointed stem end.

### **Honey Dews**

Peak season, July through September. The best honey dews start coming in July. Before then, the tendency is to pick them too soon and they never progress to the lovely, delicate sweet flavor that is characteristic of a good honey dew. This melon is quite large and may be oval to round in shape. The rind is smooth and firm. When at the peak of flavor, sweetness and ripeness, honey dews are creamy white with yellow areas—with no green at all—and have a velvety surface and a sweet aroma. It is best to buy honey dews fully ripe, rather than to depend on ripening them at home. If there is "give" at the blossom end, and the color is right, take it home and use it in a day or two. Patches of slightly raised netting mean exceptional sweetness. If honey dews are stark-white or greenish, or if they feel hard, or look shiny and smooth, they were picked too soon. The flesh should be light green and very juicy, and sweet! A good honey dew is the queen of melons. Small damaged areas will not lead to further deterioration, if you plan to use the melon immediately.

The smaller round Honeyball melon has much the same characteristics as the honey dew, except for its size.

### **Watermelon**

Peak season, May through August. Look for a slightly dull green appearance (not shiny and not really dull), with a velvety bloom on the rind. Dark green or shiny watermelons are unripe. The underbelly, where it has rested on the ground, should be yellowish or amber, not stark white or greenish. The melon should be symmetrical, with full, round ends. These signs are not totally reliable, but if used as a criterion, will usually result in the selection of a good melon. Some people use the thump test—a flat, dead sound when thumped is said to indicate ripeness. If the melon is cut, it is easier to choose—select firm, juicy flesh, with a good red color and no white streaks or mealy or softening areas; seeds should be dark brown or black.

### **Miscellaneous Melons**

There are a number of other exotic varieties of melons, which are available from time to time. If in doubt, or inexperienced with these expensive melons, look for one that has been cut open.

### **Nectarines**

Peak season, July and August. The nectarine tastes like a peach, but has the smooth, glossy skin of a plum. The color ranges from a red blush to completely red. If the color is rich and bright, it will be sweet. In recent years, I have found most nectarines to be dull in color, very hard, and impossible to ripen to an acceptable state. These nectarines have probably been picked too soon. If the color is right, but the fruit is too firm, it should ripen properly. The flesh of the ripe nectarine is yellow, like the yellow-fleshed peach. Don't buy dull-colored or shriveled fruit, or fruit with evidence of soft spots or

mold. I prefer peaches, but good quality, tasty nectarines, without the fuzzy skin of the peach, are welcome.

### **Olives**

Since olives are not available raw, all of them having been either pickled or salted, and the bitterness having been removed by potash or lye, they are not recommended for use as food. Dr. Esser says it would be a fine food in its natural state, fully ripened on the tree and sun-dried, so that some of the bitterness would be naturally removed.

### **Papayas**

Some of this fruit is available all year. Small Hawaiian papayas are available most of the time. Larger Florida papayas are best during the months of July through October (or later), depending on the weather. Papayas are also grown in Texas, and some in California. The fruit on our papaya tree usually starts ripening in the late fall, and then it is a race between the ripening and the frost (which can kill all the fruit). Size and shape of Florida papayas vary; they may weigh from one-half pound to ten pounds. The flesh may be yellow to orange-red. Select fruit that has some golden yellow or orange streaks, which is a sign that it has not been picked too green and will be apt to ripen properly. If you select papayas with at least 35% of the skin streaked yellow, they will ripen completely in two to three days at room temperature. When a papaya is totally yellow to orange and yields to gentle pressure, it is ready for eating. Don't buy mushy papayas, or fruit with dark patches, which signify age and decay. If not picked too soon and if ripened properly, the flavor is sweet and luscious. Otherwise, it may be bland and tasteless.

### **Pawpaws**

Not usually available in markets. The trees usually grow in thickets along river banks in central U.S. valleys. We picked some in Indiana. It is an odd looking fruit, cylindrical with obtuse ends, from three to five inches long and from one and a half to two inches thick. The skin is brown, with dark patches when ripe. The flesh is creamy yellow, very soft, somewhat gritty and very sweet; it contains two to eight large glossy black seeds. It is somewhat similar to the cherimoya.

### **Peaches**

Peak season, June through September. Select peaches with areas of yellow and no green at the stem, and that are fragrant, plump and fairly firm or beginning to soften. The best place and time to buy excellent, flavorful peaches is in Georgia in the summer. Don't buy hard, green peaches which were picked too soon and will never ripen properly. Ripe peaches turn reddish instead of yellow and feel soft to the gentle touch. The flesh is usually yellow, though there are some white-fleshed peaches. If you buy peaches that are ripe or almost ripe, you may find that they have deteriorated by the time you get them home. Don't buy bruised peaches. Unless used immediately, they will soon be garbage. If possible, buy local tree-ripened peaches that are slightly underripe. If you can get them organically grown, good for you! Peaches are heavily sprayed, but they can be peeled, which helps somewhat. European peaches are said to be superior to American varieties. California produces more peaches than any other of the United States.

Our peach tree produces large quantities of delicious white-fleshed fruit.

### **Pears**

Peak season, September through November. Cold storage Anjou, Bosc and Cornice pears are available as late as May. The more fragile Bartlett pears are available through November. Select firm unblemished pears. If they are too hard, they may not ripen, so there should be just a little "give" to slight pressure.

Avoid wilted, shriveled pears. Spots on the sides or blossom ends indicate an overripe or mealy pear. A ripe, crisp pear is flavorful eating, but you probably will not enjoy a hard or mealy pear. Some pears are somewhat gritty. This grittiness is not consistent by variety and may sometimes be found, in different varieties. The tiny seckel pears available in the fall are an excellent flavor treat and are never gritty. The Bartlett—a medium early pear—is large, green to yellow, and is the most popular commercial pear, though its flavor is only medium, and it becomes quite mealy if not used at its peak of ripeness. It turns yellow when ripe. The Anjou is medium to large, has smooth green skin with a faint blush. The flesh is white and sweet, with a fine flavor. It is one of the later pears. The Bosc has a long, tapering neck and a russet skin. It is juicy, with a rich aroma and fine flavor. It is a late pear. The Cornice is a choice, flavorful pear of high quality. It is available in midseason, and is large, roundish, green-yellow to yellow, with a delicate blush. Pears are not usually waxed. Scrub well before eating.

## **Persimmons**

The small native persimmon is seldom available in markets, but the trees grow wild, and if you can spot these trees, the persimmons are free for the taking in October, November and December. They are hardy, and grow in tropical or temperate climates. The fruit averages about one inch in diameter. The peak season for Japanese persimmons is October-November. They are grown in our southern states, appear in the markets in the fall, and are available for only a short time—a month or two. They are tomato- or conic-shaped, up to four inches in diameter and three inches high (sometimes wider than they are high) and orange-colored. A thin, membranous skin covers the orange-colored flesh. Persimmons are astringent when green, but become sweet when fully ripe. The flesh, when ripe, is very soft (sometimes almost liquid) and of very sweet and pleasant flavor. Japanese persimmons may have as many as eight elliptic, flattened, dark seeds, or they may be seedless. Some varieties have dark flesh, which is crisp and meaty and never astringent. These are edible before maturity. Some of the entirely dark-fleshed varieties improve as they soften, like Hyakume and Yeddo-ichi; others are best when still hard, like Zengi. But the more common, light-fleshed Japanese persimmons, or those with mixed light and dark flesh, should not be eaten until they reach the custard-like consistency of full ripeness. The "puckery" substance in the immature persimmons is tannin. As the fruit ripens, the tannin forms into crystals which do not dissolve in the mouth, and the astringency disappears. When they are thoroughly ripe, persimmons are very soft and difficult to handle. They should be picked when still a little firm, and the ripening finished at room temperature. Most of the Japanese persimmons available in the markets are picked too soon, and though they will still soften and ripen at room temperature, they never attain the optimal flavor of the persimmon which is picked at the proper time, just before they are ripe.

The small native American persimmons may also be harvested just before they are ripe, or they may be left hanging on the tree into the winter months. Even if frozen on the tree, the fruit is of excellent flavor when thawed. If the fruit is left to ripen and drop, it is at its peak, if it can be rescued quickly from the ground.

## **Pineapples**

Peak season for this fruit is March through June. Good pineapples may also be available at other times during the year. Unless pineapples are mature when picked, they will not ripen properly. They may become soft, but never sweet. They may simply rot. Select pineapples that have begun to display some gold, orange-yellow or reddish-brown coloring. Some varieties are ripe when still green, but the best and most flavorful pineapples display the change in color from the base up, as they ripen. If the yellow color has spread to 15 or 20% of the fruit, then it's ripe. A ripe pineapple should have a fragrant (but not fermented) odor and a slight separation of the eyes when ready to be eaten. The spikes should pull out easily and the fruit should be plump and heavy for its size. Soft spots or an unpleasant hint of fermentation in the odor are signs of overripe fruit. Pineapples with pointed or sunken eyes, dull yellow-green color and a dried-out appearance are immature. Fruit allowed to ripen completely before picking is a flavor treat most people in temperate climates never experience. A considerable amount of pineapples

used to be produced in Florida, as much as half a million crates, but this Florida commercial pineapple has disappeared. Most of the fresh fruit now comes from Puerto Rico, Honduras and—especially—from Hawaii. I have found Dole pineapples, air-expressed from Hawaii, to have the best flavor. They are the most expensive, but are almost always deliciously sweet and juicy. The Dole Company maintains that all their pineapples are plant ripened and that the Dole pineapple is ripe and ready to eat—regardless of shell color. I still try to pick one which is turning orange-yellow—I believe they taste best; and I always pick one that has the characteristic pleasant fragrance.

### **Plantains**

Available intermittently. These look like oversized bananas, but they must be cooked before they can be eaten. Green and yellow plantains are very starchy. They must turn black before they are mature enough to be sweet, and they must still be cooked.

### **Plums**

Peak season, July through August. Varieties of plums differ in flavor and appearance. The skins may be green to purple-red and the flesh yellow to red. There are many varieties of plums, and sometimes as many as six to eight varieties are available at the same time. During the course of the season, as many as thirty different varieties of plums may be featured in markets. Some are juicy and hard; others are soft and sweet; still others have a rich flavor. Select unblemished plums that have good color for the particular variety, a slight glow to the skin, and that yield to gentle pressure. Most plums are picked prematurely and will never reach their optimal delicious flavor. Avoid immature fruit, which is hard and poorly colored. Even if it softens, it will be very tart and lack flavor. Of course, don't buy overripe fruit which is soft, leaking and decayed. Plums are commonly waxed to give them a glossy look. It is best to peel waxed fruits. Plums should be eaten in limited amounts, because of their high content of oxalic acid.

### **Pomegranates**

Peak season is in the fall. The fruit season is all year in south Florida. Fruit is picked after it has changed color to yellow and/or dark red, and is held in cold storage to ripen. If permitted to ripen on the tree, it may split. The fruit is round and flattened, irregularly six-sided, about the size of an orange. The tough, leathery skin encloses numerous small, red, juicy flesh bodies which contain small seeds. The flesh becomes quite sweet when thoroughly ripe. Some people don't bother with the pomegranate, feeling it is too tedious and difficult to eat. A simple way to eat the pomegranate is to carefully squeeze or knead it until soft, without rupturing the skin, but liquefying the red, sweet flesh. Carefully puncture the skin to avoid squirting and suck out the delightful sweet-acid juice. When ripe, it is easy to rupture the flesh bodies with slight pressure of the thumb.

### **Rhubarb**

Peak season, March through June. Rhubarb is not recommended for use as food, because it cannot be eaten raw; even cooked, it requires much sweetening, in addition, it is a poor food because it is quite high in oxalic acid. The plant bears red petioles (fruitstalks) with large leaves, and bears no fruit in the usual sense. The fruitstalks are cooked into preserves or sauce or pie filling, and, therefore, most people think of rhubarb as a fruit, although, botanically, it is a vegetable. Diced rhubarb is usually combined with strawberries or apples for pie filling. The leaves are not used at all, as they contain large amounts of oxalic acid salts which may be fatally poisonous. As indicated above, the fruitstalks also contain enough oxalic acid to be rejected as food.

## Strawberries

Peak season is April through June. In the far south, strawberry plants may be set out either in the fall or early spring, but the fall plantings yield a small harvest. Strawberries are usually expensive and of poor quality when out of season. Medium to small berries are sweeter than large ones, as a rule. Select dry berries with stems attached, showing full, red color, bright luster and firm flesh. They should be all red, with no whiteness around the tip, and with a bright green cap. If most of the berries in a basket are of reasonable quality, it is probably the best available. Be sure to sort out any decaying or green berries as soon as possible. Don't wash them until you use them.

[Home](#) > [Lesson 24 - Selection And Storage Of Most Wholesome Foods, Part I](#) > 4. Storage Of Foods

## 4. Storage Of Foods

Foods that are refrigerated should be handled with special care. Bacteria in such foods can multiply rapidly under adverse conditions. Most of your fresh produce should be kept refrigerated (unless it needs ripening at room temperature).

Dry mixes—like Vegebase (dried vegetables used as seasoning)—which can be safely stored in a cabinet, should not be kept in cabinets above the stove.

Don't taste any food that doesn't seem right. You don't even have to swallow the food to be poisoned by the toxins produced by certain types of bacteria. In some cases, even the food's taste is no indication of safety. *When in doubt, throw it out.*

Don't expect your refrigerator to do things it was never meant to do. You may have thought that refrigeration would destroy most harmful bacteria in food. Refrigeration *will* retard the growth of the bacteria found in food, and inhibit their multiplication and ability to spread or produce a poison, but bacteria or poison present in food may still be there even after refrigeration.

The same is true for freezing, probably even to a greater extent. Freezing does not kill bacteria in food; it simply stops their spreading. The bacteria will become active and again continue to spread as the food is thawed. Food should be used as soon as possible after thawing.

Cooked foods deteriorate rapidly, even in the refrigerator. It is important to have accurate thermometers in your refrigerator and freezer. The refrigerator should be set at about 42 degrees, the freezer at zero. The motor and refrigerating unit should be kept free of lint and dirt. These substances cut off the air supply, overwork your refrigerator, and reduce efficiency.

The gaskets (the rubber insulation) around the doors should be flexible. Stiff, cracked and damaged insulation allows air seepage. Make a test with a dollar bill. Hold it halfway in the door, shut the door, and see if you can easily pull the bill out. If so, the gasket is allowing air to escape and should be replaced.

Check your freezer. Frost buildup of one-fourth inch or more actually serves as insulation against keeping foods well frozen. All items to be frozen should be tightly covered or wrapped in a moisture-resistant material.

Where you place the food is important. Some foods should be kept colder than others, and food placement affects air circulation and efficiency of the refrigerator. Keep in full view, so that you won't overlook them, those foods which should be used quickly.

It is best not to stack foods on top of one another if you can avoid it, and refrigerator shelves should not be covered with material which reduces or prevents air circulation.

Produce should be kept in the lower compartments to prevent crystalization. Food should be arranged so that the oldest is used first. This is important for safety, flavor, texture and nutrition.

Of course, the refrigerator should be kept clean and free of odors. An open box of baking soda, changed every few months, will absorb odor.

A Hygienist soon learns that it helps to have two large refrigerators. We keep the extra one in our garage. While the ideal would be to pick or obtain food for each day as needed, most of us cannot readily attain this ideal.

In order to buy and store organically grown apples by the bushel; fifteen pounds of organic potatoes and carrots at a time; a year's supply of nuts in the harvest season; a good supply of citrus fruit when the citrus season is waning, etc., these precious foodstuffs must have the best of storage facilities. This will not only minimize food losses, but will preserve as much as possible the food's value and flavor. As well as being refrigerated, they must be watched and culled, being sure to use them before they have a chance to degenerate. All of these foods store quite well, with an occasional apple or orange starting to break down prematurely. By and large, we have learned to minimize waste, and we enjoy a maximum supply of excellent food the year round, much of it organically grown.

Dr. Esser recommends that, wherever possible, the best idea is to build a large walk-in refrigeration unit in a shady spot or a place where the storage room can be set into a hill, or underground with steps leading down to the door. He gives specifications for building such a unit in his book, *Dictionary of Man's Foods*. He suggests, as one alternative, a storage room in the cellar of your house, and also gives specifications for this type of storage room. He suggests other alternatives, among which is the method we use—an extra refrigerator or two in a garage or basement.

Fresh fruits and vegetables call for careful handling. Most of them keep at maximum freshness in a refrigerator where it is cold and humid, and the sooner they are refrigerated after purchase, the longer they will stay fresh.

In discussing the storage of fresh fruits and vegetables, reference will be made to using pliofilm (plastic) bags for storage. Some Hygienists advise against the use of plastic bags or plastic anything. I don't use plastic dishes or plastic water jugs, but I still use plastic bags and plastic wrap. It is my opinion (or perhaps it is wishful thinking) that no significant transfer from plastic to food occurs, except in the presence of heat or acid. I use covered glass jars or containers whenever possible. If protecting a cut watermelon with pliofilm, people who feel very strongly against its use may thinly slice away the surface that has been in contact with the pliofilm.

The plastic storage bags available in supermarkets have proved indispensable in my kitchen. It is a good idea to double these bags, squeeze the air from the bags and close them tightly with wire "twists."

Perhaps you will like Dr. Vetrano's suggestion: Put a fine mist of water on your vegetables, put them in a brown paper bag, and then in a plastic bag.

[Home](#) > [Lesson 24 - Selection And Storage Of Most Wholesome Foods, Part I](#) > 5. Storage Of Fresh Fruit

## 5. Storage Of Fresh Fruit

Do not wash any fruit before storing, and don't remove stems first. Sort it carefully and use any damaged pieces immediately. Fruit that is purchased locally should not be bought in large quantities. A week's supply should be the maximum; more perishable fruits like peaches should be purchased in smaller amounts.

Most fruits should be held at room temperature (out of direct sunlight) until they reach the desired degree of ripeness, and then refrigerated for a few days if necessary. (Ideally, the fruit should be used as soon as possible after it is fully ripe.) Thin-skinned fruits ripening in the kitchen must be covered at night, as they may attract insects. Fruits with tough outer coverings (bananas, avocados) need not be covered. Use brown paper bags for this purpose, not plastic bags, which cut off air. Don't wash fruit until you are ready to eat it.

*Apples* may be stored in the refrigerator without prior ripening. If they were mature when picked, they will ripen in the refrigerator, and most apples will keep well—some varieties better than others. Much depends on their condition when they are stored. Usually Delicious apples are not considered good "keepers" but we have had excellent experience with our Golden Delicious apples. Maximum storage time is supposedly a few weeks, but we have ordered large enough quantities to last two months or longer, with good results.

Most ripe fruits keep best at quite low temperatures (above freezing, of course). If you set your refrigerator at about 42 degrees, it will be suitable for most of your foodstuffs.

There is one important precaution to take when storing apples. They emit a kind of ripening gas, which can spoil other foods. Therefore, apples should be stored covered, or in plastic bags, if there is any other unwrapped food in the refrigerator. Unwrapped apples will also absorb odors from other produce, and they will keep longer if stored covered or bagged.

Some fruit, such as *grapes*, *pineapple* and *watermelon*, will not ripen after picking. These should be stored unwashed in the refrigerator as soon as possible, and used within a few days. Maximum storage time for grapes in good condition is five days, but they need to be culled daily. Grapes may be stored in an open container. We use an oblong plastic refrigerator storage box. A whole ripe watermelon may be used gradually over a period of several days. A ripe pineapple should be used in a day or two.

As previously indicated, it is best to buy a ripe *honeydew melon*, instead of trying to ripen it at home. I have had the frustrating experience of holding honeydew melons for weeks—if you buy melons that do not have the signs of ripeness previously described, they may never get ripe. *Other melons*—other than watermelon and honeydew—can be ripened on your kitchen counter, then stored in the refrigerator. When ripe, use as soon as it is possible, within two or three days.

Ripe unwashed *peaches* and *nectarines* will keep fairly well in the refrigerator for a few days (if just barely ripe and not overripe). Peaches and nectarines must be carefully watched and culled.

They may be stored in an open bin or container.

Other ripe fruits may be stored in the refrigerator (*cherries*, *apricots*, *papayas*, *plums*) from several days to a week, depending on their condition when you move them to the refrigerator. Keep watching, culling and using them. Most fruits may be stored in open bins or containers.

*Berries* are very perishable, and should be bought for immediate use. Strawberries may keep a day or so, a little better than blackberries or raspberries. Blueberries, if in good condition, may keep a few days. Berries, including strawberries, must be tightly covered.

*Japanese persimmons* should be eaten when ripe; they do not keep well. They may be stored in the refrigerator a day or two after fully ripe, in a covered container. If you have too many to use before they spoil, they may be frozen successfully, but with some loss of flavor. The *small native persimmons* freeze very well; they may taste even better after having been frozen, if eaten before they are thoroughly thawed.

*Fresh, ripe figs* need to be eaten immediately—they are extremely perishable—you might be able to store them for one day in a covered container.

Once *bananas* are ripe, their life can be prolonged for several days by storing them in the refrigerator. Bananas (like apples) emanate a ripening gas and should be covered or bagged if other uncovered foods

are stored in the refrigerator. Bananas also emanate a strong odor. Bananas stored in the refrigerator will turn black and look unattractive, but they will still be "good eating" for several days. If you have too many to use up quickly, they may be frozen. Recipes for different ways to use ripe bananas will be given in Lesson 26.

*Avocados* may be stored in the refrigerator after ripening, but not too long—about three days maximum. If you find that they have gray, black or brown spots when you cut them, cut the darkened areas away and test the good-looking green part by taste. If you have too many avocados that will ripen too fast, try storing them in the refrigerator in their hard state and bring them out to ripen as needed. They will last quite a long time. This will be fairly consistently successful with avocados and will sometimes also work with *mangos*. Other fruits will usually not ripen successfully after having been chilled.

*Citrus fruit* will keep well for several weeks, sometimes much longer. They may be stored in open bins or containers in a cold room or the refrigerator. Do not store in closed bags.

*Kiwifruit* may be stored in the refrigerator for two or three days after it feels soft enough to eat. *Litchi fruit* is a little tart when mature and freshly picked. It sweetens as it ripens and should be used before the bright red outer covering starts to deteriorate. It may be stored in the refrigerator for a few days after it has attained its full sweetness. *Loquats* are tart early in the season but have a bright orange color when ripe; they are firm with a little yielding when pressed. Ripe loquats may be stored in the refrigerator for a few days. These fruits may be stored, covered or uncovered.

*Mangos* may be stored in the refrigerator when ripe, depending on their condition, and may last for quite some time, if they are still a little firm when stored. I recently had a mango that I kept in the refrigerator for two weeks after ripening and it was still perfect, sweet and luscious when it was used by my husband, Lou, the day after breaking his 29-day fast. The mango season was about over and I had saved it for him, hoping it would not deteriorate; he said it was the best one he had ever tasted.

Ripe *pomegranates* may be stored in the refrigerator for a week or so.

These storage tips are generalized, of course. You will need to develop judgment and expertise in nurturing your fruit, which will come through practice.

[Home](#) > [Lesson 24 - Selection And Storage Of Most Wholesome Foods, Part I](#) > 6. Storage Of Dried Fruit

## **6. Storage Of Dried Fruit**

All varieties of dried fruits will last a long time if properly stored in the refrigerator. Refrigerate your basic supply as soon as it arrives. Store it in tightly closed containers or pliofilm bags, transferring small amounts for current use to smaller, more accessible containers, so that the larger supply will not be subjected to frequent "out-again and in-again" changes of temperature. I have never noticed any loss of flavor, nor had any spoilage, even when I have occasionally had supplies almost a year before they were all used. I buy them mostly from Jaffe, and buy a good supply when the varieties we like are available. Of course, you should always use the oldest supplies first.

## 7. Nuts And Seeds

In nutritive value, nuts are superior to any other food that we know. According to scientific investigations by Professor Myer E. Jaffa, of the University of California; Professor F.A. Cajori, of Yale University; Van Slyke, Osborne, Harris, and others, the proteins in nuts are superior to those of animal origin.

Nuts are clean, sterile and free from putrefactive bacteria and the waste products that abound in flesh foods (uric acid, urea, etc.). Nuts are free from trichinae, tapeworm and other parasites and infections due to specific organisms.

The planting of nut and fruit trees, wherever possible, would serve a triple purpose: 1. beauty, 2. shade, and 3. excellent food.

The importance of the thorough mastication of nuts cannot be overemphasized. The nut is a dense, concentrated, high protein food and its digestion is more complicated than the digestion of fruits and most vegetables. It is important that every particle be thoroughly masticated—the stomach has no teeth, and even small particles pass through the alimentary canal undigested, because of the inability of the digestive juices to penetrate hard substances. For those with dental problems, nut butters or ground nuts, made from fresh raw nuts, are a suitable substitute.

Nuts should be regularly included in the diet, approximately two to four ounces daily, or in greater or lesser amounts, according to individual needs. Lactating mothers, and people who have undergone prolonged periods of fasting, might need a greater amount (if not beyond their digestive capability) in the initial post-fast period. People on all-raw food diets with the greater nutritional potential of all raw food, might get along well on less. People who use legumes and grains as sources for some of their protein (or cheese) should use similar amounts of nuts. The nuts, of course, should not be used at the same meals as legumes, grains or cheese. The amount of nuts used is an individual matter, subject to some experimentation.

### 7.1 Purchasing Nuts and Seeds

It is best to buy nuts in the fall, when the new crops are available. The growers, wholesalers and retailers will be handling and storing the nuts until the next fall, in any event, and it is best to obtain your annual fresh supply and do your own storing.

We buy most of our nuts from Jaffe Brothers in October. If we must fill in later, we patronize the local health food store, which does an excellent job of maintaining refrigerated supplies of shelled nuts.

Some people buy a majority of their nuts in the shell, some prefer the convenience of shelled nuts. Unshelled nuts keep longer, but shelled nuts, if properly stored, usually stay reasonably fresh all year. It is difficult to judge the quality of nuts in the shell, and some nuts are difficult to shell.

It is often possible to contact growers of locally grown nuts and purchase those nuts in season directly from the growers. If you do this, you will probably need to dry or "cure" them. This is done by spreading them in an airy place for two or three weeks. Then they will require storing in a cool, dry place. The kernels should be removed from the shells and processed as soon as possible. This is done by putting the kernels into a large flat pan (preferably in a single layer) and into a 140 degree oven for four to five hours, until they feel perfectly dry. Then they can be stored in a covered container, in the refrigerator. These fresh nuts, well-processed, will stay in top condition until the next harvest, or even longer, with no apparent loss of flavor. Not everyone is willing to go to all this trouble, and, of course, there will be varieties of nuts you wish to use that are not grown locally. When you purchase unshelled nuts, presumably they have been put through some kind of drying or "curing" process.

If you buy nuts from your local health food store, you can usually get a discount for a quantity purchase of ten pounds or more of the same variety. Sometimes, if you are a regular customer, you can get the 10% discount, even when you buy, say, only five pounds at a time.

It is usually inadvisable to purchase your nuts in supermarkets, but there are some exceptions. The shells of most unshelled nuts sold in supermarkets have been bleached, treated with lye and gas to soften and loosen the kernels, and possibly colored and waxed. Some supermarkets do carry untreated nuts and seeds. Read the labels for some guidance, but I am not sure how reliable that is.

Shelled nuts in supermarkets are not refrigerated, and unless you purchase them when the shipments first arrive, are subject to more rapid deterioration than refrigerated shelled nuts.

Since nuts are not as perishable as produce, it is a good idea to buy the best, by mail, from Jaffe Brothers or some other reliable source. They have shelled or unshelled nuts available, some organically grown, and all much better quality than are available elsewhere.

Of course, all of your nuts should be raw and unsalted. So-called "roasted" nuts are actually "French-fried" and heavily salted. You should not use "dry-roasted" nuts either. Heated fats may be carcinogenic, and nuts are high in fat.

## 7.2 Selection of Certain Varieties of Nuts and Seeds

*Pumpkin seeds* and such nuts as *macadamias*, *pignolias* (pine nuts) and *pistachios* are excellent, but usually so expensive that it is much more practical to utilize *sunflower seeds* and such nuts as *pecans*, *almonds*, *filberts*, *Brazils*, *walnuts*, *Indian nuts* and *cashews*. You can use any nuts that are raw and unsalted.

If you particularly like any of the more expensive varieties, you could have some on hand for use in small quantities, as a treat, along with other less expensive nuts. It is a good idea to use as many varieties as possible (not all together!) from time to time, because the different varieties of nuts and seeds vary in their content of nutrients, particularly certain amino acids. For example, Brazil nuts and filberts (hazel nuts) contain greater amounts of the essential amino acid, methionine, than any other nuts, while the almond contains a greater amount of the essential amino acid, valine, than do other nuts.

The bitter almond contains considerable quantities of prussic acid and is not recommended. Other varieties of almonds are excellent food, but the brown skin still contains small quantities of prussic acid, so it is best to blanch them. Blanched almonds are sometimes available, but it is much better to do your own blanching. (Instructions in Lesson 26.)

The almond is one of the best of all nuts, and a rich source of protein. It is the only one of the true nuts that has a somewhat alkaline reaction in the body.

The cashew is not really a nut—being the pistil of the cashew apple, which has been heated to make it edible—but it is used and classified as a nut.

*Peanuts*, *coconuts* and *chestnuts* are in different categories than the nuts mentioned above.

Peanuts belong to the legume family. They are not as good food as true nuts, nor do they have as good a flavor in their raw state. Some people enjoy raw peanuts and use them, but they are subject to some of the same problems encountered with other legumes (difficulty in digesting, producing gas in the digestive tract). Some Hygienists use raw peanuts (and raw peanut butter, which, when used, "should be made fresh at home and used quickly, so it does not become rancid). Ordinary supermarket peanut butter should not be used. The peanuts are made indigestible by long periods of roasting and large amounts of salt are often added. Then the peanut butter is hydrogenated, so the oil will not separate and rise to the top. Those who do not enjoy the flavor of raw peanuts and raw peanut butter sometimes use peanut butter made to order from slightly roasted peanuts in the health food stores. This is much better than the heavily roasted, salted, hydrogenated variety, but is still not recommended for regular use.

Coconuts contain the only saturated fat in the plant kingdom. Coconut meat is best when it comes from the, fresh coconut. Dried coconut which has not been treated with chemicals is available from Jaffe, Walnut Acres or your health food store. Coconut meat is alkaline in metabolic reaction.

Fresh coconuts are available in supermarkets. Their peak season is October through December.

Coconuts should be heavy for their size and sound full of liquid when shaken. Examine the eyes (the three small circles at one end). If you detect wax over one or more eyes, or any evidence of tampering, the coconut has been opened, the coconut liquid drained and the coconut refilled with water. The extracted liquid is used in manufacturing certain pharmaceuticals.

Chestnuts are available in supermarkets In the fall and early winter. The chestnut is usually roasted before eating, though some varieties (those not bitter) can be eaten raw. The chestnut is alkaline in metabolic reaction. Instructions for preparation will be included in Lesson 26.

Peanuts, coconuts and chestnuts all contain starchy protein.

The principal edible seeds are *sunflower*, *pumpkin*, *sesame* and *squash*. We use mostly sunflower seeds, which are the best buy and are very high in nutritional value. A meal containing, sunflower seeds and dark, green lettuce plus tomatoes and other nonstarchy vegetables, is excellent. If you are really concerned about getting all the nutrients at one sitting, including all the essential amino acids, this is about as close as you can get. Of course, Hygienists know that it is not necessary to get all the nutrients at one meal, and most attempts to do this result in overeating and some atrocious food combinations.

Actually, no conventional meal supplies all the nutrients, not even the much-vaunted "complete and high quality protein." Much of the food served in conventional meals is cooked or otherwise processed, thus destroying all the enzymes, and damaging and altering all the other nutrients. The so-called complete protein of animal foods would only apply to the entire animal. Muscle meats (most commonly consumed) and organ meats are deficient both in protein and calcium. After separation and heating, the amino acids from enzyme-resistant linkages, and the biological value of the protein has dropped some 50%.

A well-planned Hygienic diet does provide all of the nutrients, and provides a very favorable sodium-potassium ratio and a favorable calcium-phosphorus ratio.

No food is complete in itself, but sunflower seeds come very close. These little kernels contain practically the whole spectrum of important nutritive elements, including quality protein. They also contain about every known vitamin except Vitamin C—and even develop this one when sprouted.

Moreover, sunflower seeds contain highly digestible polyunsaturated fatty acids. They contain Vitamin E, which prevents the rancidity of the oils contained in the seeds, and this is one of the few sun-following plants which contain Vitamin D. Sunflower seeds contain generous amounts of Vitamin A, B-complex factors, Vitamin K, and a bonanza of minerals and trace elements, including potassium, iron, calcium, phosphorus, magnesium and zinc.

The American Indians used sunflower seeds for food long before white men arrived. In Middle Eastern countries, they're included as a regular course at meals, much as we serve salads. In Russia, sunflower seeds are the national snack, as regular as popcorn and peanuts here. Russian czars are said to have fed their soldiers successfully on two pounds of the seeds daily in their rations.

Sesame seeds pose some problems. They are small and perhaps difficult to masticate, and therefore some people like to grind them and sprinkle them over the salad. Unhulled, or brown, sesame seeds are somewhat toxic and should not be used. The usual hulled, white sesame seeds are even worse, because bleaches and toxic solvents are used to remove the hulls;

Acceptable hulled sesame seeds, hulled mechanically, are now available. If you want to use sesame seeds occasionally, these are the ones to get.

## 8. Storage Of Nuts And Seeds

If you buy the best and freshest nuts available, in season, you can store them until the next year's harvest. Unshelled nuts may be held at room temperature for a few months, sometimes as long as six months, except in very warm weather.

Formerly, I stored my reserve supply of nuts in the freezer, where they remained stable and fresh-tasting. We never observed any loss of flavor or texture. Of course, nuts do not freeze, even in the freezer, because their water content is very low.

When a food is frozen, its water content expands, causing bursting of the cell walls, and spilling of the contents, thus destroying the cell. When the food is thawed, a loss of texture is observed. A loss of nutrients also occurs, due to oxidation. Decomposition speedily follows thawing if thawed food is not used immediately. There is also some deterioration which occurs while the food is frozen.

Nuts do not contain enough water to expand and burst the cell walls. Nuts which have not yet been harvested seem to suffer no damage from being stored at freezing temperatures and remain fertile after having been exposed to below freezing temperatures. The question is, does the situation change after harvesting, and can the freezing temperatures then have adverse effects?

Calvin Arnold, director of Agricultural Research in Monticello, Florida, says that freezer storage is the best way to maintain the quality of pecans, in or out of the shell. He says that if they are frozen soon after harvesting, they can last several years. He warns that you should not ever try to refreeze them after thawing. This would seem to indicate that changes do occur as a result of freezing.

In March 1977, I read a report in Consumers Digest which led me to change my practice of storing nuts. This report pointed out that nutrient loss is caused by very high and very low temperatures, and that freezing temperatures particularly destroy Vitamin E. Since Vitamin E is a significant factor in nuts and seeds, I decided to discontinue the storage of nuts in the freezer. Results: excellent!

As of this writing, November 1981, I have just finished last year's supply of shelled pecans, which had been stored in moisture-proof pliofilm bags in my refrigerator, and started on my fresh supply. Amazingly, they both tasted about the same: fresh, tasty, crisp and flavorful. There was no sign of rancidity and no loss of flavor or texture from the year's refrigerator storage at about 42 degrees.

We buy our seeds (sunflower, sesame, pumpkin) as needed, usually five or ten pounds at a time, from Jaffe or the health food store, and store them in the refrigerator of course. We use more than sixty pounds of sunflower seeds in a year (two people), so we don't attempt to buy the whole year's supply at one time. We use sesame and pumpkin seeds in quite small quantities.

If you are still "sold" on storing your nuts in the freezer, you might compromise by storing a several months' supply in the refrigerator and the balance in the freezer.

Chestnuts are quite perishable. They lose moisture and spoil. If fresh, they will keep in the refrigerator, tightly covered, for up to a week.

Fresh coconuts, in the shell, will keep at room temperature for a month or more. They will keep longer, in moisture-proof pliofilm bags in the refrigerator, depending on how fresh they are. After a coconut is opened, the coconut meat will stay fresh a few days in a jar, submerged in the liquid from the coconut, or submerged in water. For longer storage, fresh grated coconut can be submerged in the coconut liquid and frozen in containers.

Dried coconut may be stored in the refrigerator, in a moisture-proof bag, for a month or longer; in the freezer, almost indefinitely. It is never a good idea to store food in the freezer more than six months to a year.

Peanuts, shelled or unshelled, will keep in moisture-proof containers in the refrigerator for at least several months. Peanut butter is a different story, of course. If you use peanut butter, it is best to make it or get it fresh in very small quantities, as peanut butter, or any nut butter, is subject to rancidity. If necessary, nut butters may be stored in the refrigerator for about a week.

[Home](#) > [Lesson 24 - Selection And Storage Of Most Wholesome Foods, Part I](#) > 9. Questions & Answers

## 9. Questions & Answers

### **Are English walnuts and black walnuts preferred varieties?**

They are both more acid in metabolic reaction than other nuts, so it would be advisable to use them only occasionally.

### **I find sesame seeds difficult to chew. Is it advisable to grind them?**

It is all right to grind and sprinkle them on your salad. Some people are able to chew them well, but if you don't, they will pass through your system without assimilation.

### **Is it better to use frozen organically grown fruit, or fresh fruit that is commercially grown?**

If it is your own fruit, and you have rushed it from the tree to the freezer, without heating, sugar or other additives, and you eat it just barely thawed, it is quite a good product, but never as good as the freshly picked fruit, eaten ripe and fresh from the tree, with no loss of flavor, texture or nutrients. If you use this frozen fruit, you should also use some other fruit that is not frozen—even though it is not organically grown—to be certain to obtain from this fruit whichever nutrients may have been damaged or destroyed in the freezing and thawing process.

### **In the winter in the north, there are few varieties, of good quality fresh fruit available. What should I do about fruit meals at that time?**

I can tell you what we do. Of course, citrus is available all winter, and it is possible to have organically grown citrus shipped from Florida. We live in Florida and use citrus regularly until melons are again available. We do realize that people who live in the north may not find citrus as agreeable or well-tolerated as people who live where the citrus grows.

I have told you how to get organically grown apples. We get enough to last most of the winter. We use some grapes, and some pears. Bananas are always available. Avocados are usually also available. Kiwifruit is now available through the year, and you can usually find pineapples also.

In the winter we usually use more dried fruit. When a variety of good fresh fruit is available, we use dried fruit only occasionally. In winter, we like to use more of the less-sweet varieties of dried fruit, such as organically grown dried apples (when we run out of fresh ones), organically grown raisins (when we don't have grapes), organically grown dried cherries, and soaked organically grown dried apricots. We also use some dates and figs, sparingly, because they are so sweet. We use only one variety of dried fruit in the course of one day.

We also use some of our frozen peaches and frozen figs from our own trees.

[Home](#) > [Lesson 24 - Selection And Storage Of Most Wholesome Foods, Part I](#) > Article #1: Does Freezing Harm Foods? By Marti Fry

## **Article #1: Does Freezing Harm Foods? By Marti Fry**

We know for certain that heating foods (that is, cooking) destroys foods by changing their chemical and organic structure. Proteins are coagulated (fused and hardened) and their amino acid molecules are broken up (deaminized), thus making them unusable. Carbohydrates (starches and sugars) become partially or wholly caramelized, though this is not readily detectable in the earlier stages of cooking. Caramelized sugars are indigestible, hence toxic to the body. Minerals are changed to their unusable and poisonous inorganic state and vitamins are largely, if not wholly, ruined.

The question arises whether the opposite extreme, freezing, likewise alters the chemical and organic structure of foods. Let's pursue this method of food preservation.

First, we should note that freezing does not affect foods of little water content—nuts, seeds, dried legumes and dried fruits lose nothing by freezing. In nature, seeds and nuts remain fertile no matter how cold it gets. The more water a food contains, the more it is adversely affected by freezing.

When a food is frozen, its water expands. This causes two immediately destructive occurrences:

1. The cell walls burst and the cell contents are spilled due to the internal water expansion; hence the cell's life is lost.
2. Oxidation occurs where air reaches the frozen foodstuff; hence nutrients are lost.

In addition to bursting the cell walls of foods and thus allowing oxidation to occur, two other things happen:

1. When the cells burst, certain of their organelles release self-destruct enzymes called lysosomes. While these enzymes are not active during freezing (and some are even destroyed), those which remain intact will speedily decompose the cell contents upon thawing. Lysosomes are in cells for the purpose of self-destructing dead cells so the dead cells will not create problems for the organism.
2. Whether oxidized or deranged by its own lysosomes, dead cells become soil for bacteria and fungi when the temperature becomes favorable again—bacteria are active at just above freezing up to temperatures around 160 degrees.

Oxidation of burst cells is the foremost cause of food deterioration during frozen storage. Frozen foods never taste as good to an unperverted palate as their fresh counterparts, even if no additives and pre-freezing treatments are employed. This is, of course, due to their deterioration while frozen.

While microorganisms such as bacteria are also inert during freezing, they become active just as soon as they are thawed. Hence, frozen foods, once removed from the freezer, decompose much more rapidly than do fresh foods. As mentioned, this is because of the bursting of the cell walls of the food when its own water expands and because of the subsequent decomposition through oxidation, self-destruct lysosomes and the final cleanup crew, bacteria.

It is well to repeat that food is rapidly destroyed when cell walls are burst, whether by cooking, blending, juicing, mashing or freezing. Oxidation occurs when cell contents are exposed to the air, and if temperatures are favorable, the cells' own lysosomes self-destruct its components.

Does this mean that banana "ice cream," fruit "smoothies" made with frozen bananas, and other frozen foods aren't truly healthful? Well, unfortunately, YES! Frozen foods have a similar effect on our organism as lightly steamed foods. Frozen foods should be used in moderation if at all. They may be helpful in inducing people to change over to their natural diet, especially people who are not willing to give up frozen treats such as ice cream Or some kind of dessert. Banana "ice cream" is a fair substitute and is far less harmful than frozen products containing additives, sugar, milk, honey, etc.

Also, remember that in our stressful environment, foods which digest quickly give us fewer problems than foods slow to digest (cooked foods, frozen foods and foods rich in oils and proteins such as nuts and seeds).

Frozen food must remain our stomach until it is warmed to body temperature. This delay can lead to fermentation of fruit sugars before the food reaches the small intestine for absorption. If we become emotionally upset (angry, irritated, annoyed, frustrated, etc.) while there is food in our stomach, digestion will be suspended and discomfort may follow.

Easily and quickly digested foods such as fresh fruits, on the other hand, will result in much briefer and less intense discomfort if you experience any stressful emotions.

Whenever you wonder which foods are best for humans, just look to nature for answers. Nature's only food storage and preservation method is drying. Fruits and berries will dry on the tree or vine if birds, insects or humans don't get to them first. Peas, beans and other legumes will dry when left in their pods. Dried foods which are frozen are not harmed because of their extremely small water content: there's not enough water to expand and burst the cell walls.

Nature provides us with food during every season. Thanks to modern transportation and refrigeration methods, people in northern climates can eat relatively fresh food the year round. Unsulphured dried fruits are available in many health, food stores. In most cases we are better off using fresh or dried foods than foods which have been frozen.

[Home](#) > [Lesson 24 - Selection And Storage Of Most Wholesome Foods, Part I](#) > Article #2: Your Probing Mind By Dr. Virginia Vetrano

## **Article #2: Your Probing Mind By Dr. Virginia Vetrano**

**I heard that sunflower seeds must be regarded as a cereal product and that, although they contain good protein, etc., they really are not good Hygienic fare and should not be used very much. What is your opinion?**

Although sunflower seeds are plant seeds, they are not grass seed. The chemical composition of cereal and sunflower seeds is quite different. Most cereals contain from 60-70% carbohydrate, 7-16% protein, approximately 7% fat and 1-3% mineral matter. The composition of sunflower seeds is 19.9% carbohydrates, 47.3% fats and 24% proteins. There is a higher percentage of protein in sunflower seeds than in cereals and a much lower percentage of carbohydrates. Sunflower seeds also contain more fat than ordinary cereals, thus making their composition more like nuts than cereal. They are very easily digested and should definitely be used in the Hygienic diet.

**I have just read of the unhealthful effects of food packaged in plastic. Is plastic next to food truly detrimental to our health?**

Yes. Foods, being composed of semi-solid materials and most of them containing acids, will

have a tendency to absorb some of the poisonous chemicals from the plastic. Food that has been adjacent to plastic should not be eaten.

Carbon, hydrogen, oxygen, chlorine, and sulphur are some of the common elements used in making plastics. The plastic chemist gets his elements from such substances as coal, petroleum, and cellulose from cotton fiber. Salt, air and water are also used. Fillers are added to the plastic resin before the finished product is made. Some fillers which are added are wood flour, cotton, asbestos, mica, and cold plasticizers are often added to make what would normally be a hard plastic into a soft pliable plastic. Coloring agents are also added. Transparent sheets of plastic are usually basically composed of formaldehyde and urea. If used with acid foods, the plastic tends to dissolve into the food and render it toxic. No fumes seem to exude from cold plastics. However, allergic dermatitis and other ailments are often developed in those working with the chemicals used in the manufacture of plastics.

**Although carnivores, whose digestion is adapted to flesh, can live successfully on a frugivorous diet, the frugivores do very poorly on a flesh diet. Is the above statement entirely true? If so, could you explain why?**

It is a well-known fact that carnivorous animals living naturally in the jungles partake mainly of fruits during certain seasons of the year. Otto Carque and many other naturalists think that, in the beginning of life, there were no carnivorous animals, and that they became so because of the ice age or other stressful changes in the environment. We see a change in dietary habits today in the anthropoid apes. As they are squeezed out of their natural grazing areas by civilization and forced to live in too small a grazing area, a few of the group will be found partaking of eggs, or termites, or ants or sometimes they will kill a smaller animal and eat it like a carnivore.

The observation indicated by the question is quite true. Carnivorous animals can be fed vegetarian diets and thrive in excellent health as a result of the diet. The reason for this is that vegetable fare produces less wear and tear on the organs of purification and elimination than does animal fare. The kidneys, liver and digestive glands are worked less and the animal is better nourished by vegetables than when he is fed flesh and animal products, cooked and lacking in alkaline minerals.

When you place man on a diet for which he is not adapted, this places a stress on his organs of purification and elimination. As he has never adapted to the carnivorous diet, his liver is smaller than that of a carnivore and he cannot detoxify and purify the poisonous products inherent in flesh food as well as a carnivorous animal. His kidneys are also smaller and become diseased from the overwork caused by a diet too high in protein and toxic material incident to the consumption of flesh, eggs and other animal products.

**Please comment on the current craze for high roughage foods, like eating bran every day.**

Many years ago Graham and other health-minded pioneers emphasized the importance of whole foods, containing all of their natural bulk. It was their idea to teach people to eat unprocessed foods such as fruit, vegetables, nuts and whole wheat containing all its bran. Constipation, they said, stems from eating foods which have been robbed of their bulk by processing.

Commercial-minded citizens soon found a means of exploiting this idea. "Put some bran in your diet and ban constipation forever." From then until now people have been prodding their bowels to action by using bran. This was not the idea behind Graham's education. He was urging that the entire diet be changed and that it include the bulk of all natural

unprocessed foods. He was not advocating fragmentation of foods.

Actually, using a lot of bran overworks the bowels, and it is totally unnecessary if one is on a natural diet containing all unprocessed and uncooked foods. Bowels will function as they should when foods natural to man's digestive tract are eaten. The whole wheat berry contains the bran natural to it. The bran is the skin of the wheat. It should be taken in proportion to the wheat if wheat is eaten, not as a fragment of a part of the wheat.

**Is the transparent skin covering each section of grapefruit and orange of any nutritional value? Should it be eaten?**

The skin covering sections of an orange may be and should be eaten with the orange, but the skin of the grapefruit has a bitter quality, and the general Hygienic rule is that if a substance is bitter to the normal unperverted palate, then it usually has a toxic quality to it and should be shunned as food, even though it may contain minerals and vitamins. The blossom of the poppy plant, containing opium, also contains minerals and vitamins. Just as the animals in the wild rely on their taste buds to guide them to their natural food, so man must rely on his sense of taste. Instinctively we do not like bitter things and would shun them if we were not wrongly educated.

[Home](#) > [Lesson 24 - Selection And Storage Of Most Wholesome Foods, Part I](#) > Article #3: Figs

**Article #3: Figs**

What a treat figs are when picked fully ripened from the tree. I have experienced this a number of times and cannot think of a meal more satisfying.

Historically, the fig has been used as food for thousands of years by many cultures throughout the Mediterranean area. This is considered to be its native habitat, although it can be cultivated in all warm, temperate zone climates.

There are four main commercial varieties: the Black Mission, the Adriatic, the Kadota and the Smyrna, of which the Calimyrna is a variety. These can be distinguished from one another by their unique coloring. The Black Mission is dark purple or black-skinned with pinkish meat; the Adriatic is green-skinned with meat resembling raspberry jam; the Kadota is also green-skinned but the meat is light colored; and the Calimyrna is gold-skinned with light brown meat. (I am not familiar with other Smyrna varieties.)

In chemical composition, the fig closely resembles that of human milk, especially in regard to the proportion of mineral salts. Quoting from Otto Carque in his masterful treatise, *Rational Diet*, he says, "While the percentage of fat in mother's milk is higher, the fig contains more fruit sugar, thus furnishing the same amount of heat units per ounce. It will also be noted that the important elements of sodium, iron and sulphur are contained in larger proportion in the fig than in milk and wheat."

"The growing child, on account of increasing muscular and mental activity, needs more of these elements to carry on the process of oxidation and elimination. These elements must be more frequently renewed than others, and a sufficient supply of them in our food is a matter of great importance. In all cases of physical and mental exhaustion, the fig is, therefore, of exceptional value in replenishing the vital forces of the body."

So if you are fortunate enough to have access to this exceptional taste treat, please enjoy figs as a, fruit

meal with other sweet fruits, or better yet, eat them alone and appreciate their unique flavor.

[Home](#) > [Lesson 24 - Selection And Storage Of Most Wholesome Foods, Part I](#) > Article #4: Imagine Avocados—As A Dieter's Delight By Lincoln Kaye

## **Article #4: Imagine Avocados—As A Dieter's Delight By Lincoln Kaye**

Avocados have an image problem.

Everybody knows they're good, but this isn't enough.

Say avocado, and most weight-conscious people say "no thanks." Let's face it—they have a lot of calories. But it's not as bad as you thought; you get a lot of nutrition for those calories.

A 1-pound avocado supplies 70 percent of an average adult's daily needs for Vitamin C, a fifth of needed Vitamins A, B1 and B2, a third of the daily Vitamin B3 requirements, and generous portions of such vital minerals as iron, phosphorus and magnesium.

All this comes at a relatively high calorie cost—about 480 calories in the 1-pound Florida avocado. This reflects the avocado's makeup, which is about 12 percent oil and 8 percent carbohydrate—more like a nut than fruit.

But, as fattening foods go, an avocado's calories are relatively "clean." The fats occur in simple, easily assimilated molecules that are cholesterol-free and low in sodium.

Avocados are among the most ideal between-meal snacks for dieters, according to experts at the Institute of Bariatrics (fat studies) at Cedars of Lebanon Hospital, Miami Beach. Since most people eat them fresh, "the essential fatty acids in the avocado remain unrefined. They retain the nitrogen compounds that act as chemical 'tags,' to let the liver know how to break down and use them.

"The fats in the avocado will not be turned into bulge. They'll become energy reserves, lining membranes for the nerves... The same goes for the carbohydrates in the avocado. They're complex carbohydrates of the type that everybody needs. The body knows what to do with them." But many remain skeptical. As one Weight Watchers International director explains it, "I'm no more of a nutritionist than anyone else in our group. We're all just former fat people."

"But I DO know that avocados are definitely off our list, at least in the beginning stages of our weight-loss program. They're simply too fatty."

The avocado is still largely unknown outside the Western Hemisphere. Europe's culinary Bible, Larousse Gastronomique, dismisses it as a nut-like fruit "much prized by the Americans."

But Latin Americans have traditionally taken a different view from Europeans, esteeming the avocado even in pre-Columbian times.

Legend has it that the 16th century Aztec emperor Montezuma entertained Hernando Cortes with a feast featuring avocados upon the conquistador's arrival in Mexico.

The Spaniards, entranced with the new fruit, were supposed to have murmured "bocados", meaning "what a mouthful!" Which accounts, we are told, for the avocado's name.

*The Random House Dictionary of the English Language* offers a different—and more plausible—story of the word's origin. "Avocado" is reportedly a corrupt pronunciation of the Nahuatl Indian word for testicle.

If so, the allusion might be to the fruit's appearance or its supposed aphrodisiac properties.

Unripe supermarket avocados can be hurried along if buried in a bin of flour or rice or put in a paper bag.

They're ripe when they yield a little to the touch. Don't wait until they start developing dark or soft spots; that means they're starting to spoil.

Never cut an avocado before it is ripe; the flesh will be hard and bitter and will never mature. Fully ripe avocados will keep for a few days chilled. They don't freeze well unless pureed.

If you're only using half an avocado at a time, leave the seed in the remaining half to keep it from spoiling in the refrigerator. After it has been cut, the fruit will discolor a little; scrub it with a slice of lemon or lime to somewhat restore its bright chartreuse color.

The avocado's leathery shell makes a natural—even elegant—dish from which to spoon the tender flesh. A halved avocado, garnished with just a little lemon juice if desired, can make a satisfying light lunch or snack unto itself.

Part of what makes it so elusive is the chameleon quality of an avocado's flavor. The cup-shaped depression left when the pit is removed is an ideal spot for adding whatever you wish. The fruit also takes on some of the flavor of whatever you add.

[Home](#) > [Lesson 24 - Selection And Storage Of Most Wholesome Foods, Part I](#) > Article #5: "Natural" Foods By Joanne Will

## **Article #5: "Natural" Foods By Joanne Will**

### **Definitions and Standards Vary Among Food Companies**

What are "natural" foods? It depends with whom you talk. The term has varied meanings to consumers. Food companies have established definitions to suit their own products. Retail outlets from food stores to health food outlets have their own idea of what "natural" foods may or may not be.

The federal government has no established standards for the use of the term, though guidelines for its use have been proposed in the food advertising regulations of the Federal Trade Commission (FTC), expected to be acted upon by Congress this fall.

But for now the term is up for grabs, and that's a confusing situation.

"Natural foods are those that do not contain any man-made substances or any chemical preservatives," says Dick Peterson, a food shopper who seeks out "natural" foods. "Fresca is a totally unnatural drink," according to Peterson. "I gave up drinking it when I read the ingredients listed on the can," he said. "It's just like Chemistry 101."

Another consumer also described the term by what it isn't. In her mind, Jell-O with its artificial coloring, flavoring and sugar, is exemplary.

Others see "natural" as foods which are organically grown with natural fertilizers. Artificial coloring is prohibited in some people's definition. Added sugar is considered a no-no by others.

Ever since the term natural became a selling point, food companies have tempted shoppers with products so labeled. But definitions and standards vary among food companies. Quaker Oats, for example, has developed a definition of natural as it applies to its products. It states that "A food or a blend of foods

derived entirely from components as they are found in nature (water lost on dehydration excepted) may be considered as natural. Such food or blend of foods may be processed to the extent that inedible or non-nutritive substances are removed, or if only inconsequential amounts of nutrients are removed, or if only the form of the food is changed."

Pillsbury discourages the use of the term natural when referring to its products, although two of them, bottled apple juice and unbleached flour, are touted as natural. Its use of the term relates to a product that has a minimal amount of processing, or as with unbleached flour, the product is "naturally" aged. Kraft uses the term natural on its cheese products to distinguish them from the processed variety. The company also has a group of dairy products promoted as natural. These products are formulated with ingredients that are not synthesized. "We try to use the term natural only as we think consumers perceive it," a legal spokesman for the company said.

If the FTC food regulations are adopted as proposed, a standard for the use of the term in advertising would provide these boundaries for determining the claims in food advertising: "Advertising shall not represent that a food is natural or a natural food if: (1) Such food has undergone more than a minimal processing after harvest or slaughter, where minimal processing may include: the removal of inedible substances, the application of physical processes (e.g., cutting, grinding, drying or pulping) that change only the form of the food; and/or processing necessary to make the food edible or safe for human consumption or to preserve it; (2) Such food contains any artificial flavorings, color additive or chemical preservative (as defined by the Food and Drug Administration) or any other artificial or synthetic ingredient; (3) Such food is composed of two or more ingredients and one or more of such ingredients could not be represented as natural or a natural food in accordance with this paragraph."

But these probably are not the final standards for advertising natural foods in the FTC regulations, which also address the use of such terms as energy and calories, organic foods, health foods, fatty acids and cholesterol. The FTC proposal has yet to be modified to reflect the opinions of consumer, food company and health food groups who responded during the public comment period.

There is concern by the FTC staff as well as such groups as the Institute of Food Technologists that if a food is labeled "natural," it will imply the product is superior to processed foods in terms of nutrient content and safety.

The Department of Agriculture in the state of Maine recently passed a regulation introduced and supported by the organic farmers and gardeners association in the state, which wanted to police their own industry. The law establishes guidelines for the use of the terms natural and organic on food labelling or advertising, and sets down definitions of "minimal processing" and "raw agricultural commodity."

It prohibits the use of the term health food on product labeling or in advertising, but allows the use of the term to identify a store or restaurant as such. Additionally, it prohibits that a food advertised as natural or organically grown make claims that it is superior in nutrient content or safety.

In Maine, growers, processors and sellers must keep records of crop locations, additions to soil, ingredients and suppliers for two years after the food is sold and which must be supplied on demand to the State Department of Agriculture.

Enforcement is left to the courts, but there are some loopholes in the law, according to Daniel Harlan, assistant to the commissioner of agriculture. The law allows for certification but does not say who will do the certifying of products. It also states that the Department of Agriculture has no "affirmation obligation" to enforce the regulation. The regulation does not go into effect until January 1980, and Harlan expects some adjustments will need to be made as "we get experience."

Whatever the outcome of the Maine regulation and the proposed federal guidelines for advertising, it's likely that fewer products will carry the term "natural" in the future.

*Chicago Tribune*

### 1. Vegetables

Vegetables are a very important part of an optimally nutritional diet, and can be the most enjoyable part of a meal if properly chosen and prepared.

Dr. Shelton says, "A large raw vegetable salad with each dinner is one of the most important elements of the diet. As a preventive of disease, it is far superior to all the vaccines and scrums ever devised."

Vegetables are anabolic (bodybuilding) foods, yet, unlike most protein foods, they are almost consistently alkaline in reaction, have very little fat and contain adequate amounts of dietary fiber.

Green leafy vegetables are the richest source of chlorophyll, as well as minerals and vitamins. They also contain small amounts of protein of high biological value, which is easier to assimilate than concentrated proteins.

A diet containing excessive amounts of protein and carbohydrates would not be nearly so harmful if balanced with a generous amount of vegetables.

Vegetables add variety to the menu and play an important role in the nutrition of humans.

#### 1.1 How to Judge and Select Vegetables

##### General Suggestions:

1. Buy in season when quality is highest and prices lowest.
2. Don't buy more than you will use before they deteriorate. The sooner you use your vegetables, the more flavor and nutritional value they will contain.
3. Handle displayed vegetables carefully so you don't damage them for others.
4. Buy the freshest and best quality available—it will taste better, you will have less to discard and you will get more usable food for your money.

Vegetables are best when eaten immediately after they are picked from the garden. Try to at least grow

some of your own lettuce (many vegetables can even be grown in crates, if there is really no garden space available), or find someone in your area who can share with you. Green leafy vegetables are so important that it is worth going to some trouble to assure a supply of the best available. All vegetables have the most to offer nutritionally and have the best flavor when organically grown and eaten in the raw state immediately after harvesting. The more time that passes after harvesting, the more chemical changes occur which alter the nutritional composition and the taste.

Fresh vegetables are usually transported rapidly from field to market in chilled vans to keep them at maximum quality. If handled properly at the wholesale and retail levels, they can reach you in fairly good condition. Unlike fruit, the concern is freshness, not ripeness. It is incumbent upon you to learn to pick the freshest and best, and to reject poor quality vegetables that have been mishandled or that have just been on hand too long. Even when you must depend on conventional sources for your produce, you can become a wise, canny, selective, knowledgeable shopper, and you and your family and dinner guests will eat the best food available.

If it's fresh, it looks fresh—not wilted, wrinkled, drooping or otherwise blemished. The color should be characteristic of the variety. The degree of maturity is also important. Most vegetables are best when slightly immature; if large and mature, they are usually tough.

As with fruits, most of the vegetables available in the markets have been treated with heavy doses of chemical fertilizers and pesticides. Washing can somewhat decrease those that remain on the outside surface, though nothing can remove the residues which are absorbed through the roots. Some vegetables can be peeled, but it is sad to have to remove the skin and thus lose the nutrients which lie immediately beneath it.

Some vegetables have their own protective coating, like podded peas and beans. Vegetables like lettuce can be washed only lightly to remove dirt and sand, and used "as is." Unless you grow your own, or obtain organically-grown vegetables, that's the best you can do. You will still be healthier and better nourished than nonvegetarians, and, as previously explained, chemical residues in the bodies of vegetarians are considerably lower than in the bodies of meat eaters.

Some vegetables may also be waxed. Watch for the wax coatings on cucumbers, tomatoes, peppers, parsnips and rutabagas. Either try to buy unwaxed vegetables, or peel them. If you must peel, don't cut too deeply. Try to discard only the thin skin. The greatest concentration of nutrients is just beneath the skin.

Red coloring may be added to sweet potatoes or to some new white potatoes. Don't buy colored vegetables.

Potatoes and onions are frequently treated with an anti-sprouting chemical. If the potatoes look fresh and good, and a few are showing signs of tiny sprouts, that would seem to indicate that they have not been treated. I pick those that are not sprouting, of course.

Tomatoes may be picked green and gassed in the van on the way to market. You can tell by the color and the taste. Tomatoes that were not picked prematurely will ripen to a deep-glowing red color, the flesh will not be mushy, and the taste will be superb.

If you locate a source of "organically grown" vegetables, check the source to try to find out if they really are as represented. Usually, there are certain indications, certain differences in appearance and taste. In any event, don't accept vegetables that are poor quality or old just because you have been assured they are organically grown.

Keep trying to find organically grown produce, but in the meantime these lessons can help you pick the freshest and best of what is seasonably available.

## **Specific Varieties of Vegetables (alphabetically):**

### **Artichokes, Globe (or French)**

Peak season is March through May. Artichokes are grown in California and, while they are shipped all through the year, they are best from March through May. This vegetable is usually cooked. Select firm, compact, tightly closed heads that are heavy in relation to size, with green, fresh-looking leaves. Size is not related to quality or flavor. You may sometimes find artichokes with frost discoloration on the outer leaves. The inner leaves are still good and unaffected. Reject artichokes with brownish soft spots near the stem or on leaf edges.

### **Artichokes, Jerusalem (or ground)**

This plant has potato-like tubers which are delicious eaten raw. It is crisp and tastes a little like a fresh water chestnut. It also has a delicate flavor when cooked. Dr. Vetrano has expressed the opinion that the starch in Jerusalem artichokes is not readily absorbed by the body.

### **Asparagus**

Peak season is March through June. Asparagus is usually cooked, but it is delicious raw. Select deep green, well-rounded spears with compact, tightly closed tips. The young slim tips are the most tender and best tasting. Avoid wilted, limp, flat or angular stalks. They are usually tough and stringy. Use asparagus as soon as possible; it is very perishable. Dr. Esser says the wild asparagus is a real delicacy. He also says that cultivated asparagus is the choicest of all spring vegetables and should be in every home garden. However, Dr. Burton has expressed the opinion that the fact that the eating of asparagus causes the urine to emit a foul odor, is indicative of this vegetable's unfavorable reaction in the body, and that he would recommend using it sparingly, if at all.

### **Beans (Fresh)**

#### **Snap Beans (Green or Wax), Pole Beans, Italian String Beans**

Peak season is May through October, particularly June and July. Available all year, but of poor quality out of season. Select beans with both ends intact. They should have a pliable, velvety feel, not hard or tough. The color should be fresh and bright-looking and the pods should be young and snap easily. If they are limp and flexible, shriveled or dull, with brown rust spots and serious blemishes, don't buy them. Young snap beans are delicious raw.

#### **Fresh Podded Beans**

Lima or cranberry beans in the pod are sometimes available. Sometimes other podded beans are available, such as fava beans. Baby limas can be eaten raw. Mature limas, cranberry beans and fava beans have a rather tough skin, and are usually cooked. Cranberry beans are very easy to hull for cooking. Fresh podded beans require no soaking, and cook in half an hour or less. Select fresh-looking unblemished dry pods.

### **Beets**

Peak season is June through August, but they are available all year. Small beets are young, sweet and tender and can be eaten raw. The roots should be firm with a smooth surface and dark red color. Wilted leaves indicate less freshness, but the bulbs, if firm, are still satisfactory.

The tops (leaves) are high in oxalic acid (like spinach) and it is not advisable to use them often. A few young tender leaves may be used in the salad. Remove the leaves as soon, as you get the beets home.

Allowing the leaves to wilt while still attached to the roots robs the roots of some nutritional value.

### **Broccoli**

Peak season is October through May. The quality of broccoli available at other seasons is not as good. (Select firm stalks with dark green or purplish green compact clusters of buds, tightly closed and not on the verge of flowering. None of the buds should be opened enough to show the yellow flower. Stems should not be too thick or tough. Avoid buds that are spread, yellow or wilted. The leaves and tender buds may be eaten raw.

### **Brussels sprouts**

Peak season is September through February. These look like miniature cabbages, but the raw flavor is not as good as that of sweet raw cabbage or broccoli. They can be eaten raw by chopping and mixing into the salad. Select tight, firm, unblemished heads with a bright green color, and no faded yellow soft or wilted leaves. If crisp and green, the outer leaves may be a little loose.

### **Cabbage**

Available all year. Supply peaks in January and runs low in August and September. Select heads that are compact and heavy, with outer leaves that are deeply colored (green or red) and free from blemishes. The outer leaves may be loose and are usually discarded, since they are very tough. If the outer leaves are missing, the cabbage is not fresh, and will probably not be sweet enough to be eaten raw. When green cabbage turns white, it is old. Dark spots also indicate age. Cabbage should be light green (or red for that variety). The three varieties of cabbage are the common green variety, red cabbage, and green savoy cabbage, which has crinkly leaves. Red cabbage and savoy cabbage are usually more expensive, but we prefer a nice, sweet, fresh head of green cabbage. Although darker colored vegetables usually contain more nutrients, Dr. Vetrano says that green cabbage is of greater nutritional value than red cabbage. Avoid cabbages that have had the butt end excessively trimmed, because this causes dehydration. Do not eat bitter cabbage—it contains irritants.

### **Carrots**

Available all year. Organically-grown carrots are often available through health food stores, but they are usually very large, overly mature carrots suitable for juicing, which is why the health food stores carry them. Young, tender carrots fresh from your garden are the best for eating raw. Carrots with the green tops still on are sometimes available in certain produce sections and, of course, they are fresh. Otherwise, select firm, smooth carrots with a good, rich, orange color. Avoid flabby or shriveled carrots, or those with large green areas. Good carrot taste comes from the bright orange area where sugar is stored. The nutritional value of the carrot makes it an important vegetable.

### **Cauliflower**

Peak season is September through November, low May through August. Cauliflower is available all year, but its price and quality are better in season. Select compact to solid heads with white to creamy white clusters (and fresh green leaves, if they have not been removed). Cauliflower accumulates black smudges as it ages. If not too many, they can be scrubbed or cut off. Cauliflower eaten raw should be the freshest possible. If it is spotted, or the green leaves are getting dark and withered, it's old.

### **Celery**

Available all year. Select crisp, thick, unblemished stalks with as many green leaves as possible. If the stalks are cracked or loose, don't buy them. Avoid limp, rusty celery. Celery is one of the best of the

salad vegetables, being succulent and juicy. Try to find celery that is medium green in color. If it is dark green, the taste is very strong, and if it is white (blanched), it is of low nutritional value.

### **Celery Cabbage (Chinese Cabbage)**

Available all year. This is an excellent salad vegetable, if not too mature and tough. Select crisp, light green heads, with no wilted, yellow leaves.

### **Chayote**

Occasionally available. This is a member of the squash family. It is light green, has white, juicy flesh, and is delicious eaten raw, like a cucumber. It is native to tropical America, but can be grown in gardens on the southeast coast, from South Carolina southward, and in southern California.

### **Chinese Vegetables**

Various Chinese vegetables are available in some supermarkets. *Celery cabbage* (listed separately) is also known as *Chinese cabbage*. The *water chestnut* (also listed separately) is another Chinese vegetable. *Bok choy* and *suey choy* are quite frequently available. Bok choy looks a little like celery cabbage, but has very dark green, wide leaves at the top. Suey choy looks like a shorter, plumper version of celery cabbage. Neither of these is as good in the salad as some other vegetables, but they are popular for use in chop suey and give a wider variety of ingredients for vegetable chop suey. Young shoots of the *bamboo* plant are much like asparagus, but are seldom found fresh in this country except in areas with Chinese and Japanese populations. Other unfamiliar but excellent Oriental vegetables, such as *Arrowhead*, *water bamboo*, and unusual squashes, may be found near these communities. Chinese vegetables are interesting and nutritionally valuable additions to the menu.

### **Chives**

A mild member of the onion family, perennial and hardy. Sometimes available in markets growing in pots. Hygienists do not recommend onions, which are irritants when eaten raw. Chives may be mild enough for occasional use by people with unimpaired digestions. Easy to grow in the garden. May be dug up, in the autumn, in small clumps, potted and kept growing in the house.

### **Corn**

Peak season is May through September. Best months vary according to local season in your area. Don't buy corn out of season. Corn begins to lose its delicate, sweet flavor immediately after harvesting, and unless it is really fresh and in its prime, it will have tasteless, starchy kernels, instead of kernels filled with sugar-sweet milk. In fact, corn is considered a green vegetable when freshly picked, and converts its natural sugar to starch in only two hours, so that it then must be classified as starchy. When freshly picked, it is delicious raw. People who buy their corn in supermarkets rarely know the fine flavor of fresh corn, but, occasionally, I have been lucky enough to be on hand for a fresh shipment of sweet, tender corn which we could enjoy without cooking. Select corn with rich green tightly folded husks, and brown dry silk. The stem should not be dry or discolored. Pull down the leaves a bit to check the kernels, which should be plumb and milky, uniform in size and color, with no bare spots. If the kernels are large, the corn is usually tough. Small, delicate kernels are the tenderest. If the milk spurts from a pierced kernel, the corn is fresh and sweet. Don't buy ears of corn which have been husked; this causes the flavor and nutritional value to dissipate rapidly. Color varies from white to yellowish to yellow, and is not a reliable indication of quality.

## **Cucumbers**

Available all year with a slight peak in May and June. If you buy cucumbers in season in your area, you will be more likely to find them unwaxed. The European or English cucumber is long and slender, has few seeds, and sometimes reaches a length of more than three feet. It is almost seedless because it is asexual, grown wholly in greenhouses. The common garden variety comes in many sizes and shapes. Small, young cucumbers are best for flavor and quality. Some supermarkets feature packages of fresh "pickling" cucumbers, which are unwaxed, small in size and contain small, tender seeds. Inspect these packages carefully; if you get them shortly after packing, before they have had a chance to deteriorate, they are excellent. If you must buy waxed cucumbers, select the smaller sizes, and be sure to peel them. Don't buy cucumbers which are beginning to turn yellow, or which have withered ends or mushy spots. Cucumbers are low in nutritional value, since they are more than 96% water, but they are good food, nevertheless, containing valuable nutrients, and are delightful additions to the salad, offsetting other more concentrated foods. Foods with high water content, like cucumbers and watermelon, help to comprise the water-sufficient Hygienic diet.

## **Eggplant**

Available all year, with a slight peak in August. The tough skin of eggplant affords it some natural protection against chemical farming. Although the skin is edible, I usually peel eggplant, because it is often waxed. If it doesn't feel waxed, and you want to use the skin, scrub it as best you can. Select firm, bright, shiny, heavy eggplants with a uniform rich purple color, with no brown or bruised spots, or cracked or shriveled skin. Select small-sized eggplants whenever possible. The larger ones are apt to be over-mature, perhaps bitter, and containing large hard seeds that are best removed. Small, soft, light seeds are fine and add to the tastiness of this food. Some people use raw slices of eggplant as a sandwich with tomatoes, sprouts and other foods as a filler, but unless the eggplant is quite young and tender, with very tiny, soft seeds, it will probably be best cooked.

## **Garlic**

Available all year. Members of the onion and garlic family are irritants when eaten raw, due to the presence of considerable amounts of mustard oil. Habitual use can impair the digestive system and weaken the organs of elimination.

Superstitions about the curative powers of garlic and onions are not based on fact. A great "purifying" process does occur when raw garlic and onions are eaten, which is a Herculean effort of the eliminating organs to get rid of the poisonous alliin and irritating mustard oil contained in these bulbs. Alliin is similar to digitalis, in that the body's reaction to the poison creates a stimulating effect to certain organs. Both of these substances get into the cells, tissues and blood. Since the body cannot make use of such poisonous substances, it calls upon the kidneys, lungs and liver to try to dispose of them, which abuses, overworks and impairs these organs. Garlic and onions are useful as companion plants in the garden to repel insects.

## **Greens (other than lettuce)**

Available all year. It is advisable to avoid foods which contain harmful substances in significant amounts—for example, foods high in oxalic acid. This poisonous substance is a calcium antagonist, and forms crystals which may develop into gallstones or kidney stones in some individuals. Please don't interpret this information to mean that if the analysis of a plant reveals minute amounts of undesirable substances, it must be stricken from the dietary. If this were true, we would be left with few foods, since some minute amounts of such substances may be found in many good foods. For instance, some over-zealous researchers have been advising against the use of lettuce, because it has been found to contain microscopic amounts of a substance resembling laudanum, a sedative. Hygienists emphatically advise the use of dark green leaves, with the exception of those containing large amounts of oxalic acid or other

toxic substances. The dark green leaves of romaine, Bibb, Boston and leaf lettuce are excellent foods and should be used in substantial quantities. *Beet greens*, *spinach*, and *Swiss chard* are so high in oxalic acid that it is inadvisable to use them as food. Small immature leaves of spinach and beet greens are lower in oxalic acid, and a few may be used in the salad. Mature *mustard greens* contain large amounts of mustard oil, an irritant. Very small mustard green leaves may occasionally be used in the salad. *Watercress* is too strong and pungent to the taste. Dr. Vetrano says that it is probably due to the large amount of sulphur it contains. Any vegetable that is strong and has a pungent, unpalatable flavor is not eaten by Hygienists. The bitter and pungent taste is nature's way of warning against them.

Young, sweet *garden chicory*, *endive* and *escarole* are suitable for salads—when mature they are bitter and contain concentrated acids and irritants. *Sorrel* has edible leaves, but should not be used because it contains much free acid, especially oxalic acid. *Pokeweed* has young purple shoots, which resemble asparagus, and is used in salads by some people. It is high in oxalic acid; contains toxic substances, and should not be used. *Comfrey* does not form a part of the Hygienic diet because it has astringent qualities which occasion actions by the body to dispose of these substances. Any plant that occasions vital abnormal actions of the body (as does comfrey) is toxic and should not be used. It is well to be alert against the potential harmful effects of the so-called herbs, which are said to have "curing" properties. Hygienists do not accept the premise that certain plants have such properties. They believe that only the self-healing power of the body, and its continual efforts toward self-preservation, can help to restore health. If certain substances cause a reaction by the body, it is because the body acts to eliminate the threat of those substances. In 1978, the English organization which had been promoting comfrey sent out a warning, saying comfrey had been found to contain pyrrolizidine alkaloids, which possibly can cause liver cancer "if eaten over a long period of time." Dr. Vetrano has been warning about the poisonous alkaloids in comfrey for a long time. Hygienists use only foods which are pleasant-tasting and mild, which have no irritating properties, and do not cause the body to react in any way other than to digest and metabolize them. So which greens (other than lettuce) does that leave that are truly good and can be recommended whole-heartedly for use in salad? Small, tender leaves of broccoli and the small tender leaves of kale are the best. Collard, dandelion and turnip leaves are also excellent when sweet, tender and immature. The mature leaves of broccoli, kale, dandelion and turnip may be cooked. If not too mature, bitter or stringy, endive and escarole may also be cooked.

### **Kohlrabi (turnip rooted cabbage)—sometimes available.**

This is grown as an annual spring and fall vegetable. It has a pale green or purple turnip-like swollen stem which grows just above the ground. It has a wonderful flavor when eaten raw and is excellent for salads. It may also be cooked.

### **Leeks**

Peak season is September, November and in the spring. The taste is similar to that of onion—only milder and sweeter, more delicate and tender. The mature plant produces a stem two inches or more in diameter, and from ten to twelve inches tall, resembling a large, over-sized scallion. As with all members of the onion family it contains the irritant, mustard oil, and should not be eaten raw unless very mild and sweet. It is usually served cooked or used to flavor soups and stews. Select crisp, firm leeks with medium-sized necks and an even, light green color.

### **Lettuce**

Peak season is March through August; available all year. *Iceberg lettuce* has a crisp texture, and the head is easier to wash than other leafy varieties that must be washed one leaf at a time. It is also the most-readily available, but it is certainly not the best. It lacks much taste, and is much lower in nutritional value than the varieties of lettuce which open to the sun's rays and produce dark green leaves. *Romaine (Cos) lettuce* has broad, tender dark green leaves and a loose head. *Butterhead lettuce*, including *Boston*

and *Bibb*, has soft, waxy-looking leaves, and is quite succulent. For those with impaired digestion, or chewing difficulties, butterhead lettuce has little fiber and is crisp and crunchy.

As an illustration of the greater nutritional value of romaine and butterhead over iceberg, consider the following figures:

	Protein	Calcium	Iron	Potassium
Romaine	1.3%	68 mgs. per 100 grams	1.4 mgs. per 100 grams	264 mgs. per 100 grams
Boston	1.2%	35 mgs. per 100 grams	2.0 mgs. per 100 grams	264 mgs. per 100 grams
Bibb	1.2%	35 mgs. per 100 grams	2.0 mgs. per 100 grams	264 mgs. per 100 grams
Iceberg	0.9%	20 mgs. Per 100grams	0.5 mgs. per 100 grams	175 mgs. per 100 grams

Iceberg head lettuce has a few outer dark green leaves, which are usually discarded, and the blanched interiors are used, most of it pale, almost white. *Leaf lettuce* or any variety of *garden lettuce* is excellent. Even iceberg lettuce grown in home gardens is greener than that found in most stores, and all the outside leaves are used.

Select fresh looking lettuce with no rusty or wilted leaves and with a minimum of damaged edges. The softer the lettuce, the sooner it should be used. Buy butterhead or leaf lettuce for immediate use. Romaine will stay crisp longer. Several varieties of lettuce should be used, varying it from salad to salad, to insure more complete mineral intake. Lettuce should be used in generous quantities.

### **Mushrooms**

Available all year with a peak season from March through May and a low July through September. Dr. Esser says that mushrooms are indigestible and generally pass through the digestive system unchanged, and although fairly rich in nutrients, little of them are usable. He says that mushrooms may be eaten, but there are many other true foods which are more deserving of a place on the menu than this edible fungus. If you use them as a novelty, or for the taste or flavor, select young (small to medium) mushrooms. The caps should be closed around the stem, and should be cream-colored or white. As the mushroom ages, the cap pulls away from the stem. Avoid wide open caps and dark "gills" (under the cap), those seriously pitted or discolored, and those with a spongy texture.

### **Okra**

Peak season is June through September. Okra is grown and marketed primarily in the south. Small, young pods may be eaten raw, but some people find them unpleasant and "slimy." Various methods of cooking reduce or neutralize the sliminess, especially by combining with tomatoes. Select small, young green pods, free from blemishes and with tips that bend with very slight pressure. They should be under three inches long, preferably smaller. Avoid pale pods and tough pods with stiff ends. As okra begins to age, it turns yellow-white, then black.

### **Onions**

Available all year, peak May through August. Ordinary yellow globe onions, which are mostly used for cooking, are quite uniform in quality. The outer, paper-like layers are thin on fresh onions, thicker on those from storage, but there isn't much difference otherwise. White onions fall into two categories—grano, which are round and granex, which tend to be flat. In general, the granos are hotter than the

granex. The larger Spanish onions (yellow or white-skinned) and Bermuda onions (purplish red) are milder and somewhat sweeter than other varieties, and are often used raw. However, as previously indicated, raw onions are irritating because of their content of mustard oil.

### **Oyster plant: (See Salsify)**

### **Parsley**

Available all year, slight peak October through December. Unless very young and sweet, parsley contains an excess of oxalic acid. It is usually as a garnish, but if young and sweet, it should be eaten since it is rich in nutrients. Select bright green, crisp leaves.

### **Parsnips**

Peak season is October through April. This is really a winter vegetable, but is on the market throughout the year, generally waxed. I don't buy waxed parsnips, but watch for the unwaxed ones. This vegetable is usually not tasty and tender enough to be eaten raw, unless very young. Select small or medium-sized, well-shaped, firm parsnips, free of surface blemishes. Avoid large ones which can be tough and woody, and those that are flabby.

### **Peas (Fresh)**

English green peas in the pod or black-eyed peas in the pod. Peak season is March through June. Small, young, fresh, bright green, recently harvested peas have the best and sweetest flavor. These will be delicious in the natural raw state, straight from the pod. Overripe peas have a flat, starchy taste, similar to raw peanuts. Select pods that are bright green and velvety to the touch. Be sure to check to see if they snap open easily. They should be well-filled without being swollen. Black-eyed peas in the pod are sometimes available, but are not popular because they are very difficult to hull. Can be eaten raw if young and fresh.

### **Edible podded peas (snow peas)**

This is a gourmet treat, somewhat expensive to buy, but very easy to grow in the garden. Use when just barely mature—they are really delicious. Select bright green, unblemished peas whose green color has not begun to fade.

### **Peppers, Sweet Bell (Green or Red) and Pimentos (red)**

Peppers are available all year, mostly green. Slight peak is June through September. Red sweet bell peppers are available intermittently, pimentos rarely. Although most of the sweet peppers on the market are green, those that are fully ripe, and much sweeter and more flavorful, have a bright red color. Buy sweet red bell peppers for immediate use since they deteriorate rapidly when red-ripe. Check carefully around the stem for softness and mold. Green peppers will keep longer. Peppers are frequently waxed. Peppers and pimentos are excellent salad vegetables and are high in Vitamins A and C. Select firm, bright, heavy, unblemished peppers with strong color and full, plump shape. Pimentos are squat-shaped, and when fully ripe, are even sweeter than ripe red bell peppers. Hot peppers, e.g., bananas, chili, jalapenos, are not recommended.

### **Potatoes**

Available year round. "New" potatoes are small potatoes, freshly harvested and often not fully matured. The outer skin is very thin. A little peeling of the skin is normal and does not affect quality. New potatoes can be white or red (or dyed red). They are very tender, high in sugar and low in starch, and

spoil rather rapidly. "All-purpose" potatoes are used in various ways, while "baking" potatoes are considered most desirable for producing the best baked potato which is not mealy or dry. As potatoes age, the skin becomes thicker, more wrinkled and drier. A smooth skin indicates a freshly-dug potato; otherwise it has been stored. It is best to bake oval, brown-skinned potatoes from storage.

Look for firm, solid potatoes with no green areas. Green areas mean the potatoes have been exposed to sun while growing, or exposed to light too long. These green spots, as well as potato sprouts from the "eyes", contain solanine alkaloids which can cause a variety of symptoms, from mental confusion to cardiac depression. If the potato has very small green areas, they can be cut off, but if they are widespread, the potato will be bitter (and toxic!) and should be discarded.

As previously indicated, potatoes have sometimes been treated with sprout-retardant, so try to find organically-grown potatoes. Otherwise, do the best you can, selecting your potatoes in accordance with instructions previously given earlier in this lesson. It is better to buy "dirty" potatoes; pre-washed ones have lost some vitamins and absorbed some water. Besides, if they haven't been washed, they may not have been treated with sprout retardant.

Immature new potatoes from the home garden are a gourmet treat. White potatoes are not suitable for eating raw; the starch should be dextrinized by heating.

### **Radishes, red or white**

Available all year, slight peak May through July. Unless young and sweet, radishes contain enough sulphur (similar to mustard oil) to irritate the digestive tract. Larger radishes are pungent in flavor and contain woody fiber which is difficult to digest and creates gas. When they are too hot to be eaten entirely alone, it is best to avoid them. People, with impaired digestions should avoid radishes altogether. If you use them, select medium-sized, firm radishes. Avoid large, flabby or spongy ones. Small red radishes may be sharper than the medium-sized.

### **Rappini**

Available intermittently. Similar to broccoli, but much stronger in flavor. It grows in long, slender stalks. We prefer the milder flavor of broccoli.

### **Rhubarb**

(Described under FRUIT—Lesson 24).

*(Note: The leaves are not used at all, as they contain large amounts of oxalic acid salts which may be fatally poisonous).*

### **Rutabagas: (see turnips)**

### **Salsify (Oyster plant)**

Sometimes available. The fleshy white roots resemble parsnips, and they taste is said to be reminiscent of the oyster. If the leaves are young and crisp, they may be eaten with the salad.

### **Scallions**

Also called green onions. Pick in May. These are a special variety of hardy onions which do not form bulbs. If young and sweet, they may be used occasionally by people with good digestions. They are usually harvested when eight to ten inches high and half an inch thick. The outer leaves are peeled off and the inner leaves with the white stems are used. If you use them, select fresh firm scallions with bright green leaves.

## **Squash**

### **Summer Squash (Soft-shelled)**

Some forms available all year. Popular varieties include *green zucchini*, *yellow crookneck*, *yellow straightneck*, and greenish-white *pattypan* (scalloped cymling squash). The small, immature squash are tender and flavorful and are excellent in salads. All parts, including seeds and skin, are edible. Select those with good color, that are heavy for their size, with a rind soft enough to puncture with a fingernail. Buy for immediate use—they don't keep well. Avoid zucchini with damaged or black spots, and yellow squash that is starting to turn orange.

### **Winter Squash (Hard-shelled, with flesh resembling sweet potatoes)**

Peak season is October and November. Popular varieties are *acorn* and *butternut*, available all year. There are many other varieties available during the winter season. Some are *buttercup*, *hubbard*, *delicious*, *banana*, *turban* and *spaghetti squash*. Select squash that is heavy for its size, with a tough, hard rind. These keep well for weeks.

### **Sweet potatoes and yams**

Available year round, peak in November, low May through July. Yams are moist and sweet with a bright orange flesh. Regular sweet potatoes are paler, less moist, and less frequently available. Select small or medium-sized ones, without cracks or damp areas. They're best if they taper at both ends. Plump ones are the most moist. They should be firm, well-shaped, with a smooth, bright and evenly colored skin, and with no wax or artificial coloring. Shriveled discolored ends, sunken, discolored areas, and wet soft spots are signs of decay. Sweet potatoes and yams decay more rapidly than white potatoes and should be bought for use in the near future.

### **Tomatoes**

Peak season June through August. Tomatoes are on the market all year, but most of them are not worth buying. The best tomatoes are generally the locally-grown varieties, which have matured and begun to ripen before picking. Tomatoes which show some red on the vine are mature. The poorest quality tomatoes are those which are picked green and ripened by ethylene gas; they are either hard or mushy, and tasteless. The crates and cartons in which such tomatoes are shipped are labeled vine-ripened, but the tomatoes are generally packed green as grass.

The skin of a good tomato is smooth, glossy and bright; the flesh is firm, but not hard. Vine-ripened tomatoes develop a deep-red color and a fresh tomato fragrance. When poor quality hothouse tomatoes are the only ones available, it is better to do without. If, on occasion, you just must have tomatoes, the hothouse varieties are better than the prepackaged hydroponic tomatoes. Hydroponic vegetables are grown without soil, using only water and chemicals. The resulting product should be avoided. Ripe tomatoes should be eaten as soon as possible. If you're selecting them to eat another day, select partially ripened tomatoes and finish the ripening at home. The small cherry or plum tomatoes are very perishable and should be used quickly. Some are highly acid, while others are almost sweet. Some are very juicy, while others are meaty and almost seedless. There are many varieties of tomatoes. The yellow and orange varieties are said to be less acid-tasting. I have never seen any white tomatoes, but I have read about them, and I understand they contain less acid than the other varieties.

### **Turnips and rutabagas**

The most popular turnip has white skin with purple shading at the top. The flesh is white. When small, tender and fine-fleshed, they are suitable for use in salads. The tops are not usually available in markets; if occasionally available they are large and mature and not suitable for eating without cooking. The best

turnip roots and leaves are the young and tender ones, fresh from the garden. Turnips should be used sparingly, because they contain a large amount of sulphur. Rutabagas are large and white or yellow-fleshed (the yellow are more common). They are members of the turnip family, but have a sweeter taste. They are usually coated with paraffin, and are not usually eaten raw. Fresh sweet rutabagas, when available without the paraffin coating, would be fine in the salad. Select turnips that are small to medium in size; firm, smooth and fairly round. Select rutabagas that are not too large and are heavy for their size, firm and round to slightly elongated. Large turnips may be strong in flavor, and coarse, pithy and fibrous. Cooked rutabagas have a characteristic taste, a little strong, enjoyed by some, disliked by others. The larger rutabagas tend to be pulpy, quite strong, tougher and harder.

### **Water chestnuts**

Available all year. Fresh water chestnuts are available in supermarkets, but very expensive. This is a delicious vegetable, with a soft, shell-like outer covering, and a sweet, white, crunchy flesh. Most people are familiar with the canned variety which is used in Chinese and Japanese cuisine. Canned water chestnuts have an unusual characteristic: they retain their crunchiness. We occasionally buy fresh water chestnuts. They sell for about \$1.50 for a container of six to eight. They are each about the size of a macadamia nut, and after paring the black shell-like skin, they are even smaller. The sweet, crisp, juicy taste is a treat.

### **Miscellaneous Vegetables**

Bags of cut-up vegetables are available in supermarkets for use in salads or chop suey. *Don't buy them.* Some contain preservatives; even if they don't, they are oxidizing, turning rusty and rapidly-losing freshness and nutritional value.

It is better to serve most salad vegetables without cutting them up in small pieces. For vegetable chop suey, cut up your vegetables as you need them. Enough nutritional value will be sacrificed in the cooking process, without starting out with limp ingredients.

I have seen sealed plastic bags of shelled black-eyed peas in water and vinegar. You will probably not be tempted to buy them, as they will most likely appear rather strange and unappetizing, just as they did to me. They are much worse than either frozen or canned black-eyed peas. As previously indicated, fresh black-eyed peas in the pod are sometimes available.

[Home](#) > [Lesson 25 - Selection And Storage Of Most Wholesome Foods, Part II](#) > 2. Storage Of Fresh Vegetables

## **2. Storage Of Fresh Vegetables**

Lettuce should be as fresh as possible. Of course the ideal would be to have lettuce picked fresh from the garden before the meal. If you are buying lettuce, get a three, or four days' supply, but wash only as needed. (If you don't want to wait to wash the lettuce at meal time, wash enough for a day or two and store in tightly closed pliofilm bags in your crisper. The stored lettuce should not be wet, nor totally dry. It will keep best if slightly moist.) Your unwashed supply of lettuce may also be stored in pliofilm bags in your crisper. The softer the lettuce, the sooner you should use it. Bibb, Boston and leaf lettuce wilt sooner than romaine.

If it is necessary to store lettuce for longer periods of time, a different method may be used. When we lived in Indianapolis, we ordered organically-grown lettuce from California in the winter once a month,

and we kept it fresh with very little deterioration for a week or longer, by storing in layers in the crisper drawer, covered by damp paper towels, watching and culling daily, and adding water to moisten the towels as they dried.

*Sweet red ripe bell peppers* and *cucumbers* are very perishable and don't keep well in bags. They tend to become slimy when bagged. I store them loose in the crisper drawer; they seem to last longer this way. Sweet green bell peppers last a little longer. I also store *tomatoes* loose in the crisper drawer.

Store *celery* or *celery cabbage* in pliofilm bags. Add a few drops of water to the bag. Don't buy more than you can use in three or four days.

*Broccoli* turns yellow in a few days. If very fresh when you get it, it may last an extra day or two. I have a very large-lidded plastic refrigerator storage box, which I find convenient for storing broccoli, *cauliflower*, *summer squash*, *brussels sprouts*, *eggplant*, etc. Always put summer squash, broccoli and eggplant on the top layer, since they are more fragile than other items. If you don't have such a box, use pliofilm bags.

*Cabbage* will stay fresh for a week or longer if stored in a pliofilm bag in your refrigerator.

For best quality *corn*, buy it the day you plan to eat it. If it must be stored, leave it in the husk, and put in a tightly-closed pliofilm bag; store it in the refrigerator.

*Eggplants* damage easily. Store in the refrigerator, but protect from bruising, as indicated previously. They will keep well for only a few days.

Store *peas* in pliofilm bags in the refrigerator; shell immediately before using. Use within a few days.

*Green beans* lose their bright green color and deteriorate rapidly. Store in a pliofilm bag in the refrigerator; use as soon as possible. The same applies to *wax beans*, *pole beans* and *Italian green beans*. They all deteriorate rapidly and should be used within a few days. If freshly picked, they may last a little longer—but if you are lucky enough to get freshly-picked beans in any of these varieties, you ought to eat them the same day, if possible, to take advantage of the freshly-picked flavor and optimal nutrition. And, since they are so fresh, you will be able to eat them without cooking.

*Globe artichokes* and *asparagus* deteriorate rapidly—use as soon as possible. Asparagus may be stored a day or two, fresh artichokes a little longer. If you must store asparagus, wrap the butt ends in a damp paper towel and place in a pliofilm bag in the refrigerator. Store artichokes in the refrigerator in a pliofilm bag.

*Jerusalem artichokes* will keep in the refrigerator in a pliofilm bag for about a week, sometimes longer.

*Okra* is quite perishable, but will keep for two or three days in a pliofilm bag in the refrigerator.

*Parsley* will stay green a few days in a pliofilm bag in the refrigerator.

*Fresh water chestnuts* are very perishable. If you buy these sweet, juicy, expensive treats, eat them right away.

*Fresh podded beans* (*cranberry beans*, *lima beans*, etc.) can be stored in the refrigerator in pliofilm bags for a few days, depending on how fresh they are. It might be better to remove them from the pods, where they tend to become slimy, if you must store them for several days.

The chayote will keep well for a week or more in the crisper drawer.

*Greens* (*kale*, *collards*, etc.) do not keep well and should be used quickly. They wilt and grow yellow. Store in pliofilm bags for two or three days.

*Kohlrabi* keeps well, like a root vegetable. Remove the tops and store in a pliofilm bag in the refrigerator.

*Mushrooms* are very perishable—it is best to use them within a day or two after purchasing; store in a pliofilm bag in the refrigerator.

*Potatoes:* Some experts on the storage of vegetables say that potatoes should be stored in a cool, dry place, but never in the refrigerator, although some of them do advise that freshly dug or new potatoes with thin skins keep best in the refrigerator.

The Department of Agriculture says that white potatoes will keep several months if stored in a cool, dark place with good ventilation at 45 to 50 degrees. Higher temperatures will cause shriveling and sprouting, and exposure to light will cause greening (evidence of the presence of solanine, a poisonous alkaloid). As previously indicated, don't buy potatoes with the "sunburned" spots. If potatoes are stored at below 40 degrees, they will dextrinize—that is, develop a sweet taste as starch changes to sugar, after which they will spoil rapidly. Cooking potatoes also serves to dextrinize the starch.

If you live in a warm climate—or for summer storage of potatoes or other root vegetables anywhere—where are you going to find a constant, dependable temperature of over 40 degrees and under 50 degrees? I have heard about root cellars for this type of storage, but, lacking a root cellar, my only solution is a refrigerator with the proper storage temperature. If I try to store them in my kitchen or on my patio, I lose them right away. My refrigerator preserves them very well. I store them in tightly-closed pliofilm bags.

*Sweet Potatoes, other root vegetables, miscellaneous:* Other root vegetables, such as carrots, turnips, rutabagas, and beets also keep best at around 40 degrees and a relatively high humidity—in the refrigerator, of course, in tightly-closed pliofilm bags. Be sure to cut the tops off your root vegetables before storing them, because the roots deteriorate as the greens wilt. If you set your refrigerator at about 42 degrees, it will be safe for all your food.

*Sweet potatoes and winter squash* are another matter—they require warmer, drier conditions, not lower than 50 degrees. It is best to keep them in a cool place in the kitchen or on the patio. Sweet potatoes will keep a few days to a week, hard-skinned winter squash a little longer.

*Summer squash* is quite perishable, but may be stored in the refrigerator in pliofilm bags for several days.

[Home](#) > [Lesson 25 - Selection And Storage Of Most Wholesome Foods, Part II](#) > 3. Purchasing And Storing Seeds For Sprouting And Ready-To-Eat Sprouts

### **3. Purchasing And Storing Seeds For Sprouting And Ready-To-Eat Sprouts**

*Alfalfa seeds, sunflower seeds, mung beans, soy beans and lentils* are the most popularly used for sprouting. They can be purchased from Jaffe or your health food store. Instructions for sprouting a variety of seeds and legumes will be given in Lesson 26.

Sprouting seeds may be stored in moisture proof containers for a long time.

It is best to sprout your own, but ready-to-eat sprouts are available in health food stores, most supermarkets, and (more and more, of late) on salad bars in restaurants.

In buying ready-to-eat sprouts, the key is freshness. Check to be sure they are crisp, not wet and slimy (thus fit only for the garbage). Good, fresh alfalfa sprouts are often available in plastic containers. Sometimes mung bean sprouts, or mixed sprouts, are also available. The alfalfa sprouts usually have the desirable green leaves; the mung beans usually do not. The mixed sprouts are not as good as individual varieties; first of all, when you sprout alfalfa, lentils, radishes, watercress, wheat and sunflower seeds together, some of them will be sprouted for too long a period for their variety, and some not long enough. (See Sprouting Instructions, Lesson 26). The mixture is also a bad one from the standpoint of food combining, and the radish and watercress sprouts are too strong, with too much irritating bite.

If you sprout your seeds at home, they may be stored in covered containers in the refrigerator for about

five days. If you buy your sprouts, be sure they are fresh and dry, and store them in your refrigerator, but don't count on their remaining in edible condition for longer than several days.

[Home](#) > [Lesson 25 - Selection And Storage Of Most Wholesome Foods, Part II](#) > 4. Selection And Storage Of Dried Grains And Legumes

#### **4. Selection And Storage Of Dried Grains And Legumes**

Cooked grains and legumes may be used in the transitional diet but should be phased out as soon as possible. They are acid forming and difficult to digest.

A large variety of dried grains is available. Rice is the most popular but, unfortunately, most people use the bleached variety. Brown rice is of much greater nutritive value and does not contain poisonous bleach residues. It also is a better value, because a cup of raw brown rice will produce considerably more cooked rice by volume than will a cup of raw white rice. Long grain rice cooks up light and fluffy; medium grain rice is slightly more starchy and moist; short grain is even stickier.

Other whole grains are available (particularly in health food stores), such as millet, barley, wheat and rye. Triticale is a hybrid between wheat and rye. Cornmeal made from corn which has not been denatured is available in health food stores, but corn and other foods which have been ground into flour or meal are not recommended, because such products are subject to rapid rancidity.

Buckwheat groats are grouped with the grains, although not really a grain, and not a "wheat." They are actually the fruit, rather than the seed (as most grains are ) of the buckwheat plant.

Wild rice is the aristocrat of grains. It is very expensive. I watch for ads in *Organic Gardening* magazine and buy it directly from producers in Wisconsin or Minnesota. Wild rice is higher in protein than brown rice.

Brown rice is probably the best of the grains (except, possibly, wild rice) and is the staple article of food in the diet of more than half of the world's people.

But all grains are excessively acid-forming and require much time and energy for digestion. Wheat, rye and buckwheat may be sprouted and eaten raw. Lesson 26 will discuss methods of cooking the various dried grains.

Jaffe Brothers carries organic brown rice, organic millet, organic whole kernel wheat, organic whole kernel rye, organic whole kernel buckwheat for sprouting, organic buckwheat groats for cooking and organic popcorn (not high in nutritional value, but relatively harmless when unsalted and not buttered).

The variety of dried legumes is large. Beans: lima, white beans (marrow, great northern, navy, pea and peanut bean), kidney, pinto, garbanzo, cranberry, azuki, black turtle, fava. Soy and mung beans are not usually found in supermarkets, but are available in health food stores. Peas: whole or split green or yellow, black-eyed, chick peas (another name for garbanzo beans). Lentils are legumes which are similar to peas.

Organically-grown unfumigated green split peas, soy beans, mung beans and lentils are available from Jaffe Brothers.

It is better to use fresh beans and peas, when available, since they have an alkaline rather than an acid reaction. Fresh legumes are easier to digest than those that have been dried, and their nutrients are more easily assimilable by the human digestive system. Dried beans become more digestible when they are sprouted. Bean sprouts may be eaten raw. Lentils seem to be tolerated somewhat better than beans by most people, but it is best to use them sprouted and eat them raw. Lesson 26 will discuss methods of

cooking dried legumes.

Store grains in moisture-proof containers or bags in the refrigerator where they can be stored for a long time. It is never a good idea to store any food for longer than six months to a year. Buy supplies as available and needed and try not to buy more than you will use in a few months. Use grains intermittently, rather than regularly; their keeping qualities are an important factor, so that several varieties can be on hand.

We prefer to use fresh lima or cranberry beans, when they are available, and of course we use fresh peas in the pod regularly, and sometimes, fresh edible podded peas.

[Home](#) > [Lesson 25 - Selection And Storage Of Most Wholesome Foods, Part II](#) > 5. Bread—General Information

## **5. Bread—General Information**

Bread is not recommended. Grain is not a Class A food, being difficult to digest, and causing "allergic" problems. Wheat, rye, barley and oats contain a substance called gluten, which is the source of many of these problems. The best way, to use grains is to sprout them and eat them raw. Wheat and rye berries and oat groats may be sprouted—the soaking and sprouting is said to neutralize the gluten, but some people still have problems with wheat and rye, even when sprouted. Oats seem to cause fewer problems, and rolled oats may be eaten raw.

Grain, ground into flour, and baked into bread along with other ingredients, including yeast and sweeteners, is not recommended. Some gluten-free breads are sometimes available, but, while these cause little or no "allergic" problems, they are still not the best food.

Oils: Eat your salads without dressings. We have been loving our salads "undressed" for many years and I make dressings only occasionally when we have guests, at which times we eat them also, and on the next day, gladly go back to our undressed salads. When I do make these salad dressings for my guests, I don't use any oil, but make them by combining, avocados with tomatoes or cucumbers. Recipes for such salad dressings will be included in Lesson 26.

[Home](#) > [Lesson 25 - Selection And Storage Of Most Wholesome Foods, Part II](#) > 6. Butter And Oil—General Information

## **6. Butter And Oil—General Information**

Butter is sometimes used to a minimal extent by Hygienists who use cooked food, but it is not recommended. If you use all raw food, you will have no need for butter.

Vegetable oil margarine is hardened by hydrogenation (see definition), and many other ingredients are added to produce an imitation of butter, resulting in an artificial product that is difficult, or impossible, for the body to deal with efficiently. Nickel is used as a catalyst when hydrogenating oils, and traces of contamination with this metal remain to be ingested. Margarine is definitely not recommended, even for occasional use.

## 7. Sweeteners

These will be discussed in detail in a future lesson. For the purposes of this lesson about the proper selection of wholesome foods, it should suffice to say that no sweeteners are recommended, together with a very brief discussion of the contraindications.

The sweeteners are: brown sugar, "raw" sugar, white sugar, milk sugar, maple syrup, molasses, date sugar, cane syrup, corn syrup and honey.

If you are on an all raw food diet, you will have no need for any sweeteners.

## 8. Packaged, Frozen And Canned Foods—General Information And Storage

The Dole Pineapple Company published a booklet in 1976 called the "Shrewd Shopper's Produce Guide." It contains much valuable information about the selection and storage of fresh produce, but, even more interesting to Hygienists are some quotations from this booklet which indicate their understanding of the superiority of fresh foods (even though the Dole Company markets canned foods as well). The following quotations could have been written by a Hygienist:

"Fresh produce provides the major portion of essential water-soluble vitamins. These must be replenished daily. Fresh produce provides bulk and fiber to help clear blood vessels of cholesterol and reduce the risk of heart disease, and fresh produce helps keep bowels functioning normally.

"Nutritionally, there is rarely a question about the superiority of fresh over processed produce. The less a fruit or vegetable is changed, including over-washing, the more food value it retains. Yet we somehow think packaged foods are more convenient—in fact, just the opposite is the case.

"Convenience" refers to the time and energy spent in preparation. Since there is very little time spent preparing fresh produce in its more nutritious, best tasting, lushest form, it certainly is one of the most convenient food forms.

"Many Americans have no idea how rich, varied and delicious fresh vegetables can be, quickly steamed...or even crisp and raw.

"One drawback with frozen vegetables is their expense. Another is that improper blanching before packaging may destroy up to 50% of the Vitamin C in vegetables; cooking destroys even more. Also, packages usually call for salted water to bring out flavor. If salt is added to vegetables during cooking, juices that carry water-soluble vitamins (like Vitamin C), minerals, sugars and flavors are drawn from the vegetables. Which means you pay more for less flavor and nutrition.

"Canned vegetables lose much of their color when they are cooked in the canning process...Each time a vegetable is reheated, it loses more of its precious water-soluble vitamins and minerals.

"Compare the cost of a ten-pound bag of potatoes with freeze-dried, instant or frozen potatoes. You may pay up to eight times more for packaged potatoes which may have lost at least 50% of their Vitamin C. Processors 'enrich' their products, but can't duplicate valuable trace elements. Moreover, because no human nutritional quantity values have been established for trace elements, there are no guidelines. Which means fresh produce is even more essential."

The advice of the Dole Pineapple Company is clear. Buy and utilize fresh produce. That is also the advice given in this lesson, and the practice of all Hygienists.

It is not recommended that packaged, frozen or canned foods ever be used, but there are always the inevitable questions about exceptions and compromises, so let's deal with them here.

Sometimes even fresh produce comes pre-packaged. Although that is not the best way to buy produce, you may occasionally buy some of these pre-packaged items. Be sure to look at the dating code.

You might buy pre-packaged dried fruits, legumes, or grains in your health food store. Read the labels. Don't buy anything containing preservatives or chemicals—or anything you don't understand.

When buying any prepackaged item, be sure the package hasn't been tampered with, or broken open.

It is possible you might be tempted to buy frozen food in an emergency. Think well before doing so. Frozen foods may have been partially thawed and refrozen in shipping and handling. And what has been added? How will it taste, compared to fresh food? If you still want to consider buying it, *read the label*. You might change your mind.

If you ever do buy frozen food, select clean packages that have no signs of having been partially thawed and refrozen.

But always remember, any time you compromise and decide to use anything other than fresh food, you are doing it for some reason other than to provide the best nutrition. *Are you sure that is what you want?*

*Storage:* If you do ever use packaged, canned or frozen food, you will need to know where and for how long you may store them. Packaged foods should be stored according to directions given for the specific item involved, usually in the refrigerator, tightly covered or bagged to keep out moisture. The fewer packaged foods you use, the better.

Frozen foods must, of course, be stored in the freezer. It is best to buy no more than you will use in the immediate future. Frozen produce is not subject to as many dangers as frozen flesh foods, but there can still be deterioration and spoilage. The fewer frozen foods you use the better.

Canned goods will, of course, keep quite a while if properly processed and if the can is not bulging, rusted, dented or otherwise damaged. *If it is bulging, don't open it, don't taste it, don't even let the contents touch your hands. The bulge indicates botulism.*

Undamaged canned goods are said to keep almost indefinitely, but it is best to use them within six months to a year. Better yet is not to use canned goods at all.

[Home](#) > [Lesson 25 - Selection And Storage Of Most Wholesome Foods, Part II](#) > 9. Questions & Answers

## 9. Questions & Answers

**I have a large organic vegetable garden and several fruit trees. Every year I have a surplus of produce in season, and share with my friends and neighbors, but still, I always have much left over. I usually freeze my wonderful organically-grown figs, peaches and strawberries without any sweetening or heating, and we eat them just barely thawed. They are delicious that way. You don't approve of buying frozen foods which may be blanched, sweetened, or otherwise treated, but what do you think about these home-frozen fruits?**

I do believe that this a good way to have some of your excellent organically-grown fruits out of season and, since there is so little loss of taste, it would be a shame to waste them. If they

are frozen quickly, immediately after picking, the vitamin loss would also be minimized. However, do not depend on your frozen fruit for your entire supply of fruit in any season. You should also use as many fresh fruits, of good quality, that you can incorporate into your diet, so that you will be sure to also get a good supply of whichever nutrients are damaged or lost by the freezing temperatures. Freezing, however, is less damaging than cooking.

**I have heard that foods which are members of the nightshade family should not be used.**

Tobacco is one member of the nightshade family. But a group of foods habitually used by Hygienists are also members of this family. These foods are white potatoes, tomatoes, bell peppers and eggplant. It is claimed that certain arthritics are "allergic" to these foods and experience remissions when they are omitted from their diet. It is also claimed, principally by advocates of macrobiotic vegetarianism, that these foods should not be used by anyone.

They advance the contention that all of these foods contain solanine (see definition). Hygienists agree with warnings against the use of potato sprouts or green areas on white potatoes, because of the concentration of solanine they contain, but not that the foods mentioned should not be used. Thousands of Hygienists do use these foods, and do not suffer with arthritis. We have used these foods frequently for many years, and we have no symptoms of arthritis or other disease.

If people who are suffering with arthritis wish to experiment with eliminating these foods from their diets for a period of time, there is no reason they cannot do so, as there is a plethora of other Hygienic foods from which to choose.

The macrobiotic diet is considered by Hygienists to be grossly inadequate, even dangerous. It consists principally of cooked grains, especially brown rice, with very small amounts of other foods. They favor the elimination of salads and fruits. They make the astounding declaration that the best diet would consist of 100% grain, but for those not eating all grain (probably no one actually does eat all grain), they allow sauteed vegetables and soup. They favor the use of salt and soy sauce, and, in spite of the thirst-producing diet of cooked food seasoned with salt and soy sauce, they recommend that very little water be taken, less than one-half pint daily.

Hygienists use very little water, since the Hygienic, mostly raw-food diet, without seasonings, is a water-sufficient diet. But it would be very difficult to abstain from drinking on the diet recommended by advocates of the macrobiotic diet.

**If I must choose between wilted, organically-grown lettuce, and fresh, crisp commercial lettuce, which is better?**

I really don't like to make such a choice, but would be inclined to say that probably the fresh, crisp commercial lettuce may taste better and have more nutritional value. If the wilted outer leaves of the organically-grown lettuce can be stripped off, exposing some green, crisp lettuce beneath it, that could be used. But if it is broken down all the way through, it is not much good.

## **Article #1: Well! You Wanted To Know By V.V. Vetrano, B.S., D.C.**

### **Is using vinegar or lemon juice, and honey with salads, then eating it with a starch, a bad food combination?**

Yes. Starches and acids should not be mixed. The enzyme, salivary amylase (ptyalin) digests starches in an alkaline medium and for a very short time only in a neutral medium. It is quickly destroyed in an acid medium. Therefore, vinegar, which contains acetic acid, interferes with starch digestion because it inactivates salivary amylase.

The reason it is necessary to insure good digestion of food is because if it isn't digested, bacteria decompose it in the stomach and intestines with the formation of toxic products. Since bacteria are living cells, they form waste products and these are very toxic to humans. These, unfortunately, are absorbed in the small intestine and cause enervation. Not being useful nutrients, these toxic wastes must be expelled from the body at a great expenditure of nerve energy, thus producing enervation. The toxemia which ensues from enervation, which checks elimination, causes destruction of normal functioning tissues of the body. Disease is the result. In addition these waste products are irritants and cause gastritis which after many years may result in ulcers and finally cancer.

Lemon juice is an acid and also upsets or impairs starch digestion. Lemon juice is not a poison, however, and if you are not eating a protein or a starch you may indulge once in a while in a little unrefined oil with lemon juice on a salad. But, if you are eating either a starch or a protein with your salad don't indulge in a dressing. For more perfect digestion it is best to always eat salads without dressings of any kind.

Strict Hygienists never use oil. Oil is a fragmented food and never as wholesome as the whole food. The term "cold-pressed" should never be taken literally. It only means the first pressing, not that the food has not been heated. Foods are heated to extract the oil from them. Heated oils become carcinogens if heated long enough, and should never touch the delicate membranes of your gastrointestinal tract.

Oils have gone through many other processes also, such as dewinterizing, deodorizing, and detastizing. These processes are aimed at preventing the oil from solidifying in a cold temperature and to give them a bland tasteless flavor, supposedly "ideal" for cooking. The odor of the original food is also processed out of it for the same reason. After all these processes, oils are no longer fit foods for people.

Honey has a singular history. Hygienists don't use honey because it combines poorly with most foods and contains formic acid (a preservative secreted by the bee), which also impairs digestion and is poisonous. Honey is lacking in the minerals necessary for humans and will cause cavities almost as easily as white sugar, besides creating an acid condition if indulged in excessively.

Modern honeys are mass produced, as are many other of our food products, and because of this, quality suffers. Beekeepers have the tendency to pinch pennies as does everyone else in business, with no thought of the consumer. They purchase old leftover candies from candy manufacturers or other businesses, melt them down and feed them to their bees, including the preservatives, shellac, coloring agents, artificial flavorings and all other poisonous

chemicals that go into candy these days. The bees in turn produce a more toxic honey. They also eventually sicken and die and the beekeeper can't understand why. With or without all the poisons, honey is food for the bee, not for people. We must eat those foods which we were designed to eat or suffer disease and die prematurely.

When we learn to eat those things to which we are physiologically and anatomically adapted, instead of searching the heavens, the oceans, forests, rivers and streams for exotic delicacies of the palate, we will begin to glow with health. Instead of wasting time searching high and low for materials out of which to artificially prepare foods for the starving world, we should be planting our gardens and orchards to fulfill this great need.

Fruits, nuts, and vegetables are the foods to which we are anatomically and physiologically adapted, and which have minerals and vitamins in proportion one to the other to meet our special needs, and we don't make a mess of the ecological system by eating them. On the contrary, we are fulfilling our part in the ecological system by eating them. By staying with the foods to which we are constitutionally adapted, we also maintain the proper cycle of the elements. Honey is not among the foods that humans should eat.

Good food combining is not that difficult to learn. Study just a little every day and soon you will know how to make your own Hygienic menus wherever you go no matter what foods are available.

### **Is the digestion of pasteurized milk difficult?**

Pasteurized milk can't be completely digested as can unpasteurized, so in that sense it is harder to digest and handle. The proteins in cooked milk coagulate, come to the surface, and form the skim with which you are familiar. Some protein is lost in the pasteurizing process, because some proteins coagulate. Coagulated protein is harder to digest than that which has not been hardened. Calcium and other minerals in pasteurized milk tend to form insoluble precipitates that are neither digestible nor absorbable, and therefore are lost to us as nutrients. With the idea of improving milk, toxic irradiated ergosterol is added. If you must have milk at least drink it unpasteurized, and take it alone.

### **Why are the nutritious foods such as watercress, comfrey and parsley not included in the Hygienic diet?**

Any vegetable that is strong and has a pungent, unpalatable flavor is not eaten by Hygienists. Any substance that can't be enjoyed by the normal sense of taste is considered toxic. The normal taste buds don't appreciate these substances and warn us against such foods that have toxic substances in them. These bitter and pungent substances are not relished normally and it is Nature's way to cause us to avoid them.

Watercress is too strong and pungent to the taste and any vegetable which is that strong should not be used because of an excess of certain substances. It is thought that the sharp taste of watercress is due to the large amount of sulphur contained therein. An excess of sulphur in foods is not healthful.

Parsley is eaten by Hygienists but it is not eaten in excess because of the high quantity of oxalic acid it contains.

Sorrel is generally used in salads, but Hygienists avoid it because it contains much free acid; especially oxalic acid. It contains between three and four parts per thousand of oxalic acid.

Comfrey does not form a part of the Hygienic diet because it has astringent qualities which occasion wasteful vital actions designed to rid the body of the toxic substance. Comfrey is used as a healing agent by herbalists because of these properties. Any plant that occasions vital abnormal actions is toxic and should not be used.

### **Do you approve of yogurt?**

Hygienists as a rule eat no yogurt. In order to make yogurt, milk has to be heated and this causes a precipitation of the minerals in the milk, rendering them insoluble and not absorbable. Consequently there is an objectionable loss of food value. Pasteurized and powdered milk is generally used for the commercial product, making it doubly poor food.

### **What is poke-weed?**

Pokeweed (*Phytolacca americana*) is a tall herbaceous plant that grows wild in North America, mainly in the Southern States. The weed has juicy purple berries and a purple root, which is used in making some drugs. The young purple shoots, which resemble asparagus, are used by some people in the spring or early summer in salads; but they are high in oxalic acid. It is best to shun any plant used as a medicine, as it always contains toxic substances.

### **The Hygienic system does not favor foods high in oxalic acid such as rhubarb, cranberries, chard, beet greens, and spinach. What actually is oxalic acid and how does it disrupt the digestion?**

Oxalic acid (C<sub>2</sub>H<sub>3</sub>O<sub>4</sub>) is an organic acid that is widely distributed throughout the vegetable kingdom. It is sometimes found combined with calcium in the form of an oxalate, instead of as a free acid. Sorrel, spinach, rhubarb, cacao, black tea and pepper contain from two to four parts per thousand in the fresh material. It was formerly thought that tomatoes were high in oxalic acid but they have been found to have less than .0005 parts per thousand. Their sour taste is due to citric acid. Cashew nuts also contain an appreciable amount of oxalic acid.

Calcium oxalate is found in the leaves of many plants that we eat, such as spinach, beet tops and swiss chard. It is also found in lichens. The oxalic acid from food will be circulated in the body in the form of a free acid or as a salt of the acid, usually a calcium salt. People in good health can oxidize the oxalic acid, that is, their bodies can break it down into carbon dioxide and water as it does other organic compounds. If metabolism is perverted by excess toxins in the body, then oxalic acid cannot be properly handled. In excess it interferes with digestion by inhibiting *enzymic* actions. If the oxalic acid is not broken down chemically before it reaches the kidneys, it may predispose to the development of calcium oxalate stones. Ragnar Berg, the Swedish biochemist states, "The amount of oxalic acid in cocoa and black tea is especially high and an over-indulgence in these drinks combined with an acid-forming diet, will greatly favor the formation, or the deposit, of urates and oxalates in the kidneys and bladder...All conditions that favor the increase of uric acid in the body, such as a high flesh diet, combined with demineralized foods, will also contribute to the formation of oxalates."

### **What is uric acid and how do oxalic acid and uric acid differ?**

Oxalic acid is a natural acid found in foods. Uric acid is a decomposition product. It is an end-product of protein metabolism.

Since the body forms its own nucleic acids and the breakdown products of nucleic acids are purines which in turn are changed into uric acid, there will always be a certain amount of uric acid in the blood, but more than what the body will form itself can be hazardous, as uric acid tends to precipitate into stones.

[Home](#) > [Lesson 26 - Preparing And Serving Foods For Best Nourishment, Part I](#) > 1. Evaluation Of The Various Stages And Methods Of Preparation Of Uncooked Foods

### **1. Evaluation Of The Various Stages And Methods Of Preparation Of Uncooked Foods**

#### **1.1 Less Is Better**

The less preparation to which foods have been subjected, the better nourishment they provide. Even when foods are not cooked, there are many methods of preparing them which are progressively more damaging to their nutritional value.

Shredding, grinding, blending and juicing all critically impair the nutritional value of the food. Even cutting up the food causes some loss of nutrients, as each cut edge is exposed for oxidation to begin. The smaller the pieces, the greater the fragmentation—the more widespread the oxidation and damage.

#### **1.2 Shredding, Grinding, Blending and Juicing**

Shredding, which produces a greater number of exposed surfaces, is obviously more destructive than cutting up. Grinding is even worse, producing smaller particles. Blending breaks the food down even more, and juicing extracts only the juice, discarding all the fiber.

All these processes deprive the body of part or all of the chewing exercise, which is necessary for the secretion of salivary enzymes and for sending signals for the secretion of gastric digestive juices.

In addition, vital food elements are impaired or destroyed. Oxidation of food is intended to occur within the body, and when it is allowed to occur before the food is eaten, the body is deprived of important elements. Blending, grinding and shredding cause significant losses of Vitamin C as the fragmented foods are exposed to the air, and as much as a 50% loss of Vitamin C within a few minutes after food is juiced.

## 1.3 Over-Washing

Even "over-washing" of fresh foods will result in significant impairment of nutritional value. Fresh foods should be washed as rapidly as possible in fresh, clean water. Fruits should be quickly scrubbed under running water. No food should be allowed to soak; this leaches valuable nutrients.

Green leaves, especially lettuce, lose crispness, quality and nutritional value if allowed to remain in water more than a few seconds. Just swish the lettuce through the water, while rubbing off the sand and dirt with your fingers; a final quick rinse is more than adequate. You don't have to eat "sandy" lettuce, nor limp, overwashed lettuce.

Nor should you use any of various substances in the water to wash off the contaminants; this creates the additional problem of removing the washing compound. If the food is organically grown, there is no problem. If it is not, you cannot do more than quickly wash it in clean water.

Nothing will remove residues of chemical fertilizers or sprays, and your efforts to do so will only further impair the produce. Get the best quality of food that is available to you, wash it quickly and enjoy! If it is selected in accordance with Hygienic principles, your health will still be better than that of conventional eaters, even though not all of your food is organically grown (and, yes, even if little of your food is organically grown).

[Home](#) > [Lesson 26 - Preparing And Serving Foods For Best Nourishment, Part I](#) > 2. Priority Of Food Preparation

## 2. Priority Of Food Preparation

Recapping the various stages of raw-food preparation prioritizes them in the following order:

1. The best food is that which is eaten raw, whole, and fresh from the garden or orchard, after a quick washing in clean water.
2. A minimum amount of separation of leaves for washing, or cutting of vegetables, performed immediately before eating, will result in minimum impairment of nutritional value.
3. Cutting up vegetables for a tossed salad, or fruits for a fruit salad, will result in considerable impairment of nutritional value, because every cut edge is exposed to oxidation and loss of nutrients. If such vegetable or fruit salads are occasionally desired, they should be prepared immediately before the meal.
4. Shredding, producing a greater number of exposed surfaces, is even more destructive. If shredding is temporarily necessary because of dental or digestive problems, it should be done at the table, immediately before eating. Attractive, efficient shredders for table use are available.
5. Grinding or blending breaks down the food even more. Sometimes, blended salads may be resorted to as a temporary measure, to tide one over dental, digestive, or other special problems, but the habitual use of blended salads is not advisable. If blenders or food processors are used in the preparation of special recipes, for occasional use, it should be done with the full knowledge that the nutritional value of these foods has been greatly diminished. If this is but an occasional practice and the major part of the diet consists of whole, raw foods, the principal negative will be subjecting the organism to digesting foods which do not provide maximum nutritional return.
6. Juicing foods and discarding all the fiber is contraindicated, except for use in breaking some prolonged fasts or where extreme debility makes the use of juiced foods necessary. The occasional use of juiced fruits or vegetables, in small amounts, twenty to thirty minutes before a meal, isn't harmful. Habitual use of large quantities of juiced foods is highly inadvisable. Juices bombard the body with large quantities of fragmented nutrients in much the same way as food

supplements do, and the effects can be negative and even positively harmful. In addition, the body is deprived of the opportunity to chew, assimilate and metabolize the complete foods which are sources of optimal health.

We receive many requests for special recipes for transitional food programs to provide greater variety in a raw-food diet, and for ideas and instructions in the preparation of special menus and treats. Such menus, recipes, ideas and instruction are therefore included in this lesson.

It is hoped that the student will gradually realize that simple meals are the best, and will come to delight in luscious fruits, vegetables, nuts, seeds, and sprouts. Included in this lesson is a special section on sprouting.

[Home](#) > [Lesson 26 - Preparing And Serving Foods For Best Nourishment, Part I](#) > 3. Preparation Of Foods Without Cooking

### **3. Preparation Of Foods Without Cooking**

#### **3.1. Fruits**

##### **3.1.1 Fresh Fruits**

Most fresh fruits should be served whole after scrubbing under running water. What can rival the appeal to the eye and to the taste than a bowl or tray of beautiful, colorful, fragrant whole fruit?

Apples, pears, peaches, nectarines, apricots and plums should be served whole, with sharp knives for peeling and cutting if necessary or desired. The fruit should be eaten unpeeled whenever possible, but if fruit is not organically grown, it is a difficult choice.

Grapes and cherries, of course, require no preparation other than washing.

Some citrus fruit is easy to peel (tangerines, murcotts, mandarins, tangelos, temples). Other citrus may be cut at the table. No sugar on grapefruit! (Nor other sweetening.)

Berries should be served whole. Serve strawberries with caps and stems attached. No sugar! (Nor any other sweetening.) Fruit that is not sweet enough to eat without added sweeteners is not ripe enough to eat.

Serve persimmons whole—fully ripe, soft and luscious. I like to cut this fruit in half and spoon away from the skin. My husband, Lou, just bites into the fruit, discarding the skin as he eats.

Nature provided bananas with a wonderful coat, protective and easy to remove—no problems there. Serve them golden, brown-freckled and whole.

Cut ripe, buttery avocados in half at the table and eat with a spoon out of the half (or quarter) shell. If you want to peel the avocados, quarter them and remove the skins from each quarter. Serve the sections on a platter, or arrange them on lettuce leaves or other salad vegetables. Serve fresh, soft, ripe figs whole.

Serve delightful, emerald kiwi fruit whole. Cut it in half at the table and spoon out of the half shell.

Fresh litchi fruit is easy to peel at the table. Loquats require no peeling.

Florida papayas are sometimes very large. Cut in wedges and remove seeds immediately before serving. I have seen some people eating the seeds of the papaya, and heard them stoutly maintain that the seeds

are "loaded" with nutrients and should not be discarded. I believe the taste of papaya seeds is ample evidence that they are not intended to be eaten. The plethora of nutrients which they undoubtedly contain are intended for the fruit which the seeds are programmed to produce.

Just-right ripe mangos are a treat any way you serve them. They can be cut in half, slicing over the large flat seed on both sides and eaten with a spoon. They can be peeled and sliced, but don't waste whatever clings to the peel and seed, though you may have to hang over the sink to eat it.

Joy Gross demonstrated (at the American Natural Hygiene Society national conventions) an attractive way to serve mangos. With a sharp paring knife; score the flesh of the halved mangos in cubes, without cutting through the skin. Invert the two halves (turn them inside out). Beautiful! And delicious!

Melons, of course, will have to be cut immediately before serving. Small melons may be served whole.

Prepare pineapple immediately before serving in the following manner: Cut a thin slice from the bottom. Cut in quarters lengthwise, either leaving the top on as a decoration, or removing it. Prepare each quarter as a separate serving by separating the flesh from the skin with a sharp knife and slicing the remaining wedge into segments. Serve on the rind (pineapple boats). Serve with forks for removal of the segments and serrated grapefruit spoons for scraping out any flesh remaining on the rind. Don't put the rind to your mouth—use a spoon. The eyes of the rind are razor sharp and can cut your lips, mouth and tongue.

Pomegranates may be served whole, and may either be cut and eaten in sections, cutting into segments as you eat, or the juice may be sucked out through a carefully punched hole (look out, it'll spurt all over you) after carefully kneading it until it is entirely soft. Don't be too rough, you may inadvertently break it open.

### **3.1.2 Dried Fruits**

Dried fruit may require some advance preparation.

Dates and raisins may be presumed to be clean enough to eat as they come from a sealed package. For those who doubt this, a quick rinse just before eating may allay their misgivings.

Dried figs are usually soft enough to eat without preparation. Rinse, if desired. If figs are hard, they may be soaked in distilled water for several hours, or over night.

Dried apricots and peaches are greatly improved by overnight soaking. In fact, unsulphured apricots and peaches are almost inedible unless they are soaked.

Dried apples are very tasty—not too sweet. Soaking makes them too mushy.

Dried prunes, cherries and pears may be used either way—as they are, or soaked.

Dried bananas are excellent as they come from the package—soaking is not necessary or desirable.

Dried litchi fruit needs no preparation—just crack open the nut-like outer skin and find the raisin-like fruit inside.

Dried carob pods are sometimes too dry to be really palatable, but usually are soft enough to chew on. I have not tried soaking them.

### **3.1.3 Fruit Recipes (Without Cooking)**

Ideally, recipes (especially for fruit) are not necessary nor desirable. We know that many people will want fruit recipes for a variety of reasons:

1. A nostalgic yearning for "mixtures".
2. For variety.
3. As a replacement for junk foods (to satisfy "cravings").
4. A desire to prepare something "fancy" or "convenient" to serve guests.

5. For reluctant family members.
6. For children (of any age).

These might also work out better for parties or groups of people, because they are perhaps more economical, more convenient, or more "liberal" for conventional friends.

## **Fruit Salad**

*Acid Fruit:* Oranges, pineapple, strawberries and kiwi fruit. This can be prepared an hour or two in advance to serve to guests. The juice from the oranges should keep the other fruit from drying out or discoloring. Use whole strawberries, fairly large pieces of fresh pineapple, and orange sections. Serve slices of kiwi fruit alongside—don't put the kiwi fruit into the salad. Or use the decorative slices of kiwi fruit as a garnish.

This salad can be served to luncheon guests, along with nuts or avocado along with a salad bowl of romaine lettuce, buttercrunch lettuce and celery. (Of course, these same foods could be served more Hygienically by putting out bowls of oranges and strawberries, platters of pineapple boats and kiwi fruit halves, along with the bowls of greens and platters of avocados or nuts if desired.)

*Other Acid Fruit Combinations:* Winesap, Jonathan or other tart apples. Put cubes of mild cheese on toothpicks and arrange in a circle on each apple. (Or just serve trays of apples and trays of avocados, nuts or cheese.) Serve with bowls of lettuce and celery.

Oranges, avocados and romaine lettuce—this combination is an excellent meal any time of the day.

*Subacid and Sweet Fruit:* Combine berries (blackberries, raspberries, etc.—not strawberries) or dark sweet cherries or dark purple grapes with two or three of the following: sliced papayas, peaches, nectarines, apricots, sweet plums, apples, pears.

If this can be prepared immediately before serving to guests, arrange fruits attractively on romaine lettuce leaves, either on platters or individual service plates.

If it must be prepared an hour or two in advance, put together as a fruit salad, and moisten with apple, cherry or grape juice. For this purpose, you may have, to use bottled juice from a health food store, which usually does not contain additives, and will be of quite good taste and quality, although, of course, usually pasteurized. Or add dried soaked cherries or apricots and the juice in which they have been soaked.

This fruit salad can be served with, ripe Japanese persimmons, whole ripe bananas (or you can add sliced bananas to the fruit salad just before serving), and either avocados on the half or quarter shell or platters of dates, figs, raisins or other dried fruit. Also set out a salad bowl of two varieties of lettuce and some celery.

### **3.1.4 Papaya with Subacid Fruit Salad**

Fill halves of large papayas with subacid fruit salad for a party buffet. Or fill wedges of large papayas or smaller papaya halves with subacid fruit salad for individual servings.

### **3.1.5 Papaya, Avocado and Apple Salad**

Arrange wedges of papaya, avocado and apple (sweet or tart) in a circle on a bed of romaine or Boston lettuce.

### 3.1.6 Party Melon

A very attractive way of serving melon buffet style with less of the mess of rinds is to cut open and shape a watermelon as a basket with a handle. That is, instead of cutting it in half, make the cuts lengthwise a little short of the halfway mark, to leave a handle-like section about three inches wide.

Melon balls can be made of the red flesh, but a better way is to cut small wedges and arrange them in the watermelon basket, along with wedges of several other varieties of melon, such as honeydew, casaba, cantaloupe, etc. Don't mix any other fruit in the watermelon basket. Instead, provide bowls and trays of other varieties of fresh fruit for those who don't wish to partake of the melon, or for those who sometimes mix melon with other fruit at the same meal.

This is excellent for an afternoon reception or evening party.

### 3.1.7 Other Entertaining "Tricks" with Fruit

(Sometimes combined with other uncooked foods)

Although the following are not cooked, their nutritional value has been substantially impaired by blending, freezing, etc. These recipes are provided as alternatives to conventional cakes, pies, puddings, ice creams and other desserts.

*Compote or Pudding:* Soak dried figs (or dried apricots) overnight. Remove stems and blend with the soak water. Add fresh (or frozen) bananas and blend. If too thick, add distilled water—if not thick enough, add more bananas. Serve topped with sliced bananas. The fig pudding will be quite sweet, the apricot pudding less sweet. This may also be made by blending bananas with any other subacid or sweet fruit. Keep very cold until served. This may be served with fresh subacid or sweet fruit (not acid fruit or protein).

*Apricot-Prune Whip:* Soak dried apricots and pitted prunes overnight. Blend the next day with the soak water. Serve plain or with sliced bananas.

*Frozen Banana Treats:* Break ripe bananas in halves or thirds. Dip in carob syrup (carob powder mixed with distilled water) and then roll in grated coconut, and freeze. These may be eaten without thawing—they do not freeze hard. Remove from freezer about ten minutes before eating.

*Raw Applesauce:* Wash, quarter and core sweet juicy apples (do not remove skins). Put in blender a few pieces at a time with a small amount of apple or grape juice. Other fruits maybe combined with the apples. This should be prepared immediately before serving, to keep color and flavor, or keep very cold until served.

*Banana "Ice Cream":* Whenever you have a surplus of ripe bananas, peel and freeze them while in tightly-closed plastic bags. They may be converted to "ice cream" by putting them through a Champion juicer (using the homogenizing blank instead of the juicing screen); or in a blender. The Champion juicer method is preferable. The blender method may require a small amount of liquid to get it started. Other frozen or fresh fruit may be combined with the bananas (peaches, cherries—not strawberries).

## 3.2 Nuts

### 3.2.1 Shelled vs. Unshelled

Ideally, nuts should be served in the shell, with nutcrackers, picks and bowls for debris. Some people prefer the convenience of shelled nuts, and, if they are purchased fresh, in season, and properly stored, I must admit to their many advantages—especially in the case of the hard-shelled varieties.

Pecans, almonds, walnuts and Filberts are easy to shell, but the quality of the shelled varieties is more uniform. Shelled nuts, of course, take up less space, and are, therefore, easier to store. Shelled nuts are

easier to serve, easier to eat, and there is no debris to clear from the table (and usually the floor, as well).

Pistachios in the shell (whenever available unsalted, which is not often) should be shelled as you eat them. They are so easy to shell that there is no excuse for buying them shelled, unless you just can't find any unsalted, in the shell. Interesting note: Dr. Shelton says that, unlike most other protein foods, pistachios are non acid-forming (alkaline-forming when digested).

Indian (monkey) nuts are tedious to shell. Pignolias (without shells) have a taste similar to that of Indian nuts.

Sunflower seeds are available in or out of the shell. They are tedious to shell, usually done with the teeth.

### **3.2.2 Shelling Suggestions**

Special nut crackers are available which simplify the opening of hard-shelled nuts like Brazils, hickories and macadamias. Black walnuts are a special problem and usually must be opened with a heavy hammer on a large stone. I have heard it suggested that black walnuts be well wrapped and laid in the driveway, so that the car could be run over the package. A vise might be the best solution for cracking black walnuts.

Another suggestion for cracking hard-shelled nuts appeared in *Organic Gardening* magazine. The suggestion is to soak them for ten or fifteen minutes in a hot (or boiling) water bath prior to cracking. If they have been dried and stored for several weeks, sprinkle with water and place with a damp cloth in a tight container for twelve to twenty-four, hours before cracking. This will also soften the nutmeats for removal in larger pieces.

### **3.2.3 Blanched Almonds**

Most almonds should be blanched, as their brown skins contain a strong astringent (prussic acid). Almonds which do not have a bitter taste are relatively safe to consume in limited quantities, but it is still better to remove the skins.

To blanch, put almonds in a large strainer with a handle. Dip in boiling water for about one minute; then dip in cool water. If this does not loosen the skins sufficiently, repeat the process. Skins should slip off easily.

If the almonds are not bitter, and it is not convenient to blanch them at the particular time, the skins may be partially scraped off with a sharp knife. You might also like to scrape some of the brown skin off filberts or Brazils, which may improve the taste, though these skins are not toxic. Dr. Shelton recommends removing the skins of Brazil nuts.

Although most nuts are acid in metabolic reaction, Ford Heritage and other references list almonds as being alkaline in metabolic reaction. Dr. Shelton (*The Hygienic System, Volume II, Orthotrophy*, p. 147) disagrees, and says that almonds are definitely acid-forming, although not so much so as animal proteins. The comparative degrees of acidity of nuts with animal proteins are: walnuts (one of the most acid nuts) 8; chicken, 11.2; beef, 9.8; eggs, 12.

The only nuts Dr. Shelton calls alkaline-forming are the pistachios. Although the skin of the almond contains prussic acid, and should be removed, Dr. Shelton recommends it as one of the finest of nuts.

### **3.2.4 Ground Nuts and Nut Butters**

Sometimes, dental, digestive or other problems may necessitate the preparation of ground nuts or nut butters—or these might be needed for young children. Children should learn to chew their nuts (thoroughly) at as early an age as possible.

*Ground Nuts* are quite dry. If they are to be used, it may help to use a half grapefruit along with a serving

of ground nuts. Squeeze some of the juice over the ground nuts, and roll some of the grapefruit sections in the nuts. This results in quite a palatable meal.

Another possible way to use ground nuts is to eat with whole strawberries, dipping each bite of strawberry into the ground nuts.

*Nut Butters:* To make nut butters, grind the nuts in nut mill or blender a little longer (beyond the ground nut stage). This produces an oilier mixture which can be patted into a butter with a spoon. The longer and finer you grind the nuts, the oilier they will be. If necessary, add a very small amount of oil after removing from the grinder. Sesame oil (buy cold-pressed) is a pleasant-tasting and more stable oil.

It would be better to make nut butters without the use of added oil. Try a tiny amount of distilled water instead, and see how you like it. Almond, pecan or sesame butter may require a little oil (or water). Cashew butter or peanut butter are oily enough without it. (Peanuts are not really nuts, but are starchy proteins, similar to legumes. Neither are cashews really nuts, being the pistils of cashew apples.)

Brazil nut butter is too oily by itself, but mixes well if ground with walnuts. The taste of each is improved by the combination.

*Nuts 'n' Seeds Butter:* Sunflower seeds and sesame seeds have an excellent taste when used whole, but, somehow, they are less tasty when ground into butter. They combine well in a nuts 'n' seeds butter. Use one cup of nuts (any kind except cashews or peanuts), one-half cup of sunflower seeds and one-half cup of sesame seeds. Grind together. A very small amount of oil (or water) may be necessary.

Nut and seed butters may be served on celery strips, lettuce leaves, sweet pepper slices, cucumber slices or other nonstarchy vegetables, or they may be eaten with a spoon.

### **3.2.5 Nut Milk**

(Sometimes used for infants or for special problems.)

2 cups water

1/2 cup nuts

Blend as thoroughly as possible. If this is to be used for an infant, it may be necessary to strain it through cheesecloth.

### **3.3 Coconuts (Classified as Starchy Protein)**

To open a coconut, drive a clean large nail through two of the three "eyes" or soft spots, and drain off the liquid. The liquid may be filtered through filter paper (coffee filters are fine) to remove any bits of husk, and it may be drunk immediately or stored in the refrigerator a short time, not more than a day or two. The shell may be cracked with a hatchet or hammer, or in a vise. If the coconut is placed in the freezer for an hour or so before cracking (after removing the liquid), it will crack and come away from the shell more readily.

Break up the meat in small pieces and eat out of hand. The pieces may be stored a short time in the coconut liquid or in water (not more than a day or two).

Peel the pieces before eating if you have trouble with tough skins. Coconut maybe grated if used shortly after preparing. Grated coconut may be used in salads.

Coconut is sometimes used with sweet fruits. (See recipe for nondairy coconut carob ice cream.) While coconut with sweet fruit is not an ideal combination, it seems to work out fairly well, in most cases. Don't use coconut with nuts or with acid or subacid fruits.

Unlike most nuts, coconuts are alkaline in metabolic reaction. Coconut oil, unlike other vegetable fats, is naturally highly saturated.

The only other saturated vegetable fat is palm oil, which you will find included in the labeling of many packaged products. The label usually says "one or more of the following oils has been used in the preparation of this product: corn oil, cottonseed oil, palm oil...." So it is impossible to tell which oil has actually been used. Palm oil, like coconut oil, is highly saturated.

The fact that coconuts contain saturated fat is not a contraindication for their use as food. This information, however, is of value in planning a diversified Hygienic diet. Saturated animal fats are not recommended. Fresh coconut is an excellent food.

### **3.3.1 Coconut Milk**

Some people who find coconut meat difficult to chew may enjoy using this palatable coconut milk occasionally.

Blend two cups warm distilled water with one-half cup fresh peeled coconut, and cool in refrigerator. Blend again and strain through cheesecloth or Nylon mesh. If stored in refrigerator, it will separate, but may be stirred with a spoon before drinking. Do not store more than a day or two.

### **3.3.2 Coconut Milk Shake**

Blend one cup coconut milk with one small banana and/or one tablespoon carob powder and/or several dates and/or two ounces sweet cherry or sweet grape juice. The juice adds an extra "fillip." The amounts and combinations of ingredients depend on how sweet you like it.

## **3.4 Chestnuts**

Chestnuts are starchy protein, and are alkaline in metabolic reaction. They are usually "roasted," but may be eaten raw if they are a nonbitter variety. To remove the thick skins, blanch in boiling water and let stand about two minutes. Remove a few at a time from the water and cool slightly, then peel with a paring knife. Roasting will also loosen the skins. Recipe for roasting chestnuts will be included in the lesson on cooked food recipes.

## **3.5 Vegetables**

### **3.5.1 Finger Salads**

Most vegetables may be served raw and as nearly whole as possible with no dressing as part of a "finger salad." They should be washed immediately before serving.

These vegetables include, but are not limited to, all varieties of lettuce; celery; all varieties of cabbage; celery cabbage; cucumbers; carrots; sweet peppers and pimentos; tomatoes; Jerusalem artichokes; English peas; edible podded peas; young, tender green beans; broccoli florets and leaves; cauliflower; young turnips; young, tender beets; young, tender kale, collard or turnip greens; yellow crookneck squash; zucchini squash; sweet potatoes or yams; asparagus; young, tender sweet corn. A few vegetables are not particularly tasty when used uncooked, such as Brussels sprouts, eggplant, okra, globe artichokes and white potatoes, although some people do use these raw. White potatoes should not be eaten raw, but should be steamed or baked to dextrinize the starch.

Combine three to five vegetables as a salad for one meal.

### **3.5.2 Salad Dressings, Dips and Spreads**

(Vegetables Combined with Nuts, Avocados, etc.)

If you must have salad dressing (get out of the habit as soon as possible), the following are better than

bottled salad dressings or the use of vinegar.

1. Blended tomatoes with avocado
2. Blended tomatoes with cashew nuts (or other nuts or seeds)
3. Avocado with diced cucumbers (Optional: add lemon juice or Vegebase)
4. Yogurt or sour cream, Vegebase, diced cucumbers
5. Yogurt or sour cream, avocado! Vegebase
6. Avocado "butter"—(mashed avocado with optional lemon or lime juice)
7. Equal parts of Vegebase and Oil
8. Lemon and oil

Some of these dressings may also be used as dips or spreads (or guacamole—avocado dip).

### **3.6 Additional Recipes for Vegetables Combined with Nuts, Avocados, etc.**

#### **3.6.1 Rollups**

For this, use one or two large leaves of romaine lettuce, and choose from a variety of fillings:

*Choose one of these:*

Avocado  
Nuts (Ground or whole)  
Seeds (Ground or whole)  
Cheese (if you use it)

*Combined with one or more of these:*

Tomatoes  
Sweet Pepper Strips  
Cucumber Strips  
Celery Strips  
Sprouts

Roll up the filling inside the lettuce leaves, wrapping it up. This may be eaten like a sandwich.

#### **3.6.2 Individual Meal-in-One Salad Bowls**

Medium-sized pieces of lettuce (two or three varieties)

Cut-up red cabbage

Sliced sweet red pepper or pimento

Sliced celery

Choice of sliced young tender zucchini or other summer squash or a few broccoli florets

Choice of a few edible podded peas or young tender green peas or a few olives

Garnish with pignolia nuts and sunflower seeds and alfalfa sprouts or raw milk cheese slices and avocado slices and alfalfa sprouts.

Serve with Vegebase and oil dressing or cucumber sour cream dressing, if desired.

#### **3.6.3 Coconut Treat**

Combine optional amounts of:

grated coconut  
grated carrot  
grated cabbage  
chopped celery

(if desired, a few raisins may be added)

Moisten with coconut liquid or coconut milk (or yogurt, if you use it). This may be served with a large green salad and globe artichokes for a satisfying company meal.

### **3.6.4 Other Entertaining Salads**

For entertaining, you might serve trays of finger salad with salad dressings on the side. Or serve large bowls of salad cut up as little as possible, with salad dressings on the side. Or serve celery sticks with dips.

## **3.7 Preparation of Salad Vegetables**

Leaves of lettuce or other greens may be separated under running water, rinsing away as much of the sand and dirt as possible, assisted by your fingers. A quick dip in a sinkful of cold water and another quick rinse should clean up the sandiest leaves.

The more delicate buttercrunch lettuce varieties (Bibb, Boston) should be handled carefully and washed even more quickly to avoid losing crispness and nutrients.

Lettuce should never be soaked in plain or acidulated water. This will only extract the vitamins and make it limp and unappetizing.

Separate celery strips from the stalk, rinse under running water, dip in cold water, using brush at the same time to dislodge the dirt from the crevices. Another rinse should finish the job. Discard pithy or damaged portions.

Remove the tough outer leaves from cabbage and you will usually find a clean head underneath. Rinse the head if you like, and cut wedges for serving.

Remove celery cabbage strips as needed. A quick rinse and brushing will clean them up quickly.

Scrub cucumbers with a vegetable brush. Remove peeling, if waxed. I don't use waxed cucumbers. Some supermarkets carry packages of "pickling cucumbers" all through the year—small, unwaxed cucumbers with small seeds. If they are fresh (and they often are), they taste like fresh-picked garden cucumbers, and the peel is tender and edible.

Scrub carrots with a brush—don't peel. Small, young ones are best for salad. If you can find them with the tops still on, those are freshest. If you must shred your carrots, do it at the last possible minute.

Tomatoes—ah, tomatoes! When they are good, they are very, very good, and when they are bad they are horrid.

Hydroponic tomatoes? Thumbs down! Hothouse tomatoes? Not much better—sometimes barely acceptable. Deep red, vine-ripened tomatoes? Oh, yes! Wash them under running water, serve whole and enjoy!

If you must slice or quarter tomatoes, do so at the table, or at the last possible minute before serving.

Red or green sweet peppers (preferably ripe and red, which are the sweetest) and pimentos: wash under running water and cut in half to inspect condition. This is necessary, because deterioration may exist without outward signs. If deterioration has occurred, cut away ruthlessly, and use only firm, hard flesh.

Scrub Jerusalem artichokes or sweet potatoes (or yams) vigorously. Serve in small amounts in the salad. The artichokes are crisp and easy to eat. If you must shred the sweet potatoes, do it as close to eating time as possible.

Edible podded peas need only a quick washing. English peas: serve fresh young garden peas in the shell. If they are larger and from the supermarket, you may prefer to hull and cull them.

Broccoli and cauliflower florets need only a quick rinsing or dip in water and perhaps a little cleaning up

with a sharp paring knife. The smaller broccoli leaves are also a bonus salad vegetable of high quality. The larger, tougher leaves require some steaming.

Small young turnips may be scrubbed and served whole—also, small young beets.

Small young green beans should be washed quickly and culled.

Asparagus should be rinsed, dipped and rinsed again to remove the sand.

Scrub yellow crookneck and zucchini squash lightly to avoid damage.

Strip husks and silk from young, tender sweet corn—you might use a tooth brush lightly. Rinse, and enjoy.

Raw mushrooms may be used in salads, but are not recommended because they pass through the digestive system unchanged. If used, wash by holding briefly under running water. If necessary, finish cleaning up with a sharp paring knife. Do not soak or peel.

[Home](#) > [Lesson 26 - Preparing And Serving Foods For Best Nourishment, Part I](#) > 4. The Sprouting Garden

## 4. The Sprouting Garden

A sprout is a germinating seed. It is the tiny shoot that emerges from the seed, the first visible evidence of the materials stored within the seed, programmed to create life.

I don't agree with people who believe sprouts to be the most perfect food—I am inclined rather to go along with Dr. Shelton's belief that sprouts should be regarded as an excellent bonus food, but not to be relied upon as a replacement for foods grown to a more mature state, with benefit of earth and sunlight.

Cathryn Elwood's chapter on "Vitamin-Rich Sprouts" in *Feel Like A Million* gives excellent information on the progressive and accelerating nutritional value as the sprouts progress.

### 4.1 Advantages of Sprouting

Sprouting is fun! It is exciting to watch the growth (in a jar or other type of sprouter on your kitchen counter) into vitamin-, mineral- and protein-rich green vegetables, loaded with enzymes and chlorophyll. As the tiny seeds multiply in volume (one to two tablespoons of alfalfa seeds fill a quart jar with sprouts), a wonderful salad ingredient, with an abundance of Vitamins A, B and C, is being grown. Alfalfa sprouts are also a splendid source of Vitamins D, E, G, K and U. Vitamin C is especially high in lentil and mung bean sprouts after three days. However, lentil sprouts should be harvested when the sprout is no longer than the seed, while mung bean sprouts should be allowed to grow long enough to produce green leaves.

The sprouted seed contains far more vitamins than the dry seed, multiplying dramatically through the sprouting period. Research at Cornell University and the University of Pennsylvania revealed phenomenal increases of Vitamin C as sprouting progressed, and an increase in Vitamin C even during storage in the refrigerator. Riboflavin, niacin and other B vitamins were also increased during sprouting.

Dr. Paul Burkholder of Yale University found that the total Vitamin B content is increased 100% during the sprouting process.

Vitamin-conscious people, please take note; Hygienists need not be concerned, leaving that to nature and the Hygienic diet.

Sprouts are also noted for their high-enzyme activity. During germination, proteins are broken down into amino acids and some new protein is synthesized. During sprouting, much of the starch is converted to natural sugars. In many seeds, fats disappear and are replaced by carbohydrates, improving tremendously the digestibility of sprouts over seeds.

Phytic acid in whole grains is antagonistic to the absorption by the body of calcium, iron and other minerals. Soaking and sprouting neutralizes the phytic acid, so sprouted grains not only provide increased nutrients, but elimination of the threat of phytic acid also.

Viktoras Kulvinskis says that iron may become unavailable to the organism due to the resultant insoluble compound formed when the iron unites with phytic acid. "The acid combines well with calcium, iron, zinc and other minerals, which reduce significantly their absorption into the bloodstream. Similarly, oxalic acid of spinach can reduce significantly the availability of calcium. Phytin is very frequently present in many seeds and may constitute up to 80% of the phosphorus content of the seed. The absolute amount of phytin varies in species and families. Hence, eating a diet rich in seed, besides the high protein complications, can result in a tremendous loss of important minerals, in spite of the fact that seeds are rich sources of such minerals. However, the mineral losses because of the high phytin concentration become insignificant if one sprouts the seeds."

Professors A.M. Mayer and A. Poljakoff-Mayber of the Botany Department, Hebrew University, Jerusalem, found that most of the phytin disappeared in the sprouted seeds studied and that there was an increase in desirable forms of phosphorus compounds, especially in lecithin.

The dry seed is characterized by a remarkably low metabolic rate, but even the moistening of the seed triggers tremendous changes. Drs. Mayer and Poljakoff-Mayber describe the process which results in such important changes: "As soon as the seed is hydrated, very marked changes in composition in its various parts occur. These changes occur even when the seed is placed in water without any nutrients, and in complete absence of assimilation. The chemical changes which occur are complex in nature.

They consist of three main types: the breakdown of certain materials in the seed, the transport of materials from one part of the seed to another, especially from the endosperm to the embryo or from the cotyledons (the first pairs of leaves) to the growing part, and lastly the synthesis of new materials from the breakdown products formed. The only substances normally taken up by the seeds during germination are water and oxygen."

Cathryn Elwood says, "One of the chief advantages lies in the fact that sprouting can give us a new crop of delicious food every two to four days—a crop that needs no thought to soil conditions, composting techniques, blight, bugs, weeds, storms, sprays; one that can be grown any season and in any climate and is simple to harvest and store for future use." She says they have valuable protein, compare favorably with fresh fruits in antiscorbutic (Vitamin C) properties, have no waste, are excellent raw (and could be lightly cooked, if desired, in about three minutes). One pound of seed increases to six or eight pounds of food, and so the price drops way down.

All sprouted seeds, legumes and grains can be eaten without cooking. Some people find sprouted soybeans unpalatable, in which case they may elect to steam them briefly to slightly alter the taste.

"Sprouties," as Cathryn Elwood calls them, are not only convenient, economical, easily grown—any time, anywhere—they are also an easily available source of organically-grown food. If you do not use organically-grown seeds, be sure they are, at least, untreated.

## **4.2 Miscellaneous Sprouting Information**

I have found alfalfa seeds, sunflower seeds, mung beans, azuki beans and lentils easiest to sprout; we like alfalfa sprouts best and use them freely, mostly with salad vegetables. Many people with impaired digestions, who have trouble with other nuts and seeds, find that sprouted sunflower seeds are well tolerated.

Garden peas, soy beans, garbanzo beans and wheat and rye berries may also be sprouted, with just a little experimentation and practice. Most whole nuts, seeds, beans and grains may be sprouted, although shelled nuts are difficult, sometimes impossible, to sprout. As previously indicated, all may be eaten raw after sprouting, and may be stored in the refrigerator for about five days. Sprouted beans, raw or cooked, are less gassy than unsprouted beans, which, of course, must be cooked.

Eat sprouts from rye, wheat or other grain berries (seeds) in 24 hours or so, when but a short sprout is showing. (Grains sour readily.) Harvest sunflower seeds when sprouts are no longer than seeds, preferably even shorter. Eat lentils in two or three days, sprouts no more than one inch, preferably less.

Garbanzo and soy bean sprouts are especially high in protein but are not easy to work with; sprouts should be short—they also may sour. Rinse frequently to preclude souring, say, four times daily, even more if weather is hot.

Lentil sprouts are also high in protein, and they are easier to handle.

Mung beans are easy to sprout and will be ready in about four days, with sprouts about two inches long and showing green leaves (see sprouting instructions).

Alfalfa sprouts will also be ready in about four days, with sprouts of about two to three inches and green leaves.

Seeds and legumes for sprouting are available in health food stores, also in some supermarkets. Don't sprout mixed varieties, because different seeds, legumes and grains require different treatment.

### **4.3 Sprouting Instructions**

This is the simplest and easiest sprouting method: Wash seeds thoroughly. Put one to two tablespoons of alfalfa seeds (or three to six tablespoons of beans, or one-half cup of wheat, rye or other grain) in a quart jar with the purest possible water (preferably distilled) about three times the volume of the seeds. Soak overnight, or six to ten hour (alfalfa, lentils and wheat or other grains about six hours; mung, garbanzo or soy beans ten hours or longer). Soak longer in cool weather, less in warm weather. The soak water should not be cold. One source advises changing the water should not be cold. One source advises changing the water halfway through the soak period.

Cover the jar with a stainless steel mesh and jar ring, or cheesecloth or nylon mesh held on with rubber bands or a jar ring. (The jar ring has a tendency to rust before long, so the rubber band is somewhat better in that respect).

Next morning (or at the end of the soaking period) drain and rinse the sprouts (without removing the mesh covering). Set at an angle to drain (prop up bottom end of the jar about an inch). Then rinse two to four times daily through the mesh; fill the jar with water from the tap, empty and shake very gently to disperse the seeds around the jar. I will repeat: sprouts require more frequent rinsing in warm weather, less frequent in cooler weather. Cover the jar with a small towel so that the seeds will have air and warmth, but not light, as they put out their first roots.

### **4.4 Alfalfa Sprouts and Mung Bean Sprouts**

After three days (or when leaf appears), remove towel so light (not direct sunlight) will green up the leaves (chlorophyll). This may take eight to twelve hours or more, after which they may be eaten or stored in the refrigerator to eat at a later time. Actually, they may be eaten at any stage in the sprouting process, but they are at their best when the twin leaves are dark green. Only alfalfa and mung bean sprouts are sprouted to the green leaf stage. Other sprouts are used sooner, without green leaves, per previous instructions.

When sprouts are ready for harvesting, hulls may be floated off, if desired. In any event, the sprouts should be given a final rinse, and then allowed to drain on a paper towel before storing. They will keep

longer if stored only slightly moist, not wet.

## 4.5 Use of Soak Water

You will note that I have recommended using the soak water for your plants. Although the soak water has been found to be rich in minerals, vitamins, enzymes and amino acids, it is foul-tasting. Some people advocate drinking this soak water, or using it by combining with other foods.

Dr. Alec Burton (Australian Hygienic Professional) believes that this soak water should be regarded as a waste product and discarded, but there is certainly no reason not to make use of its nutrient content for your garden, which will then return the nutrients to you when you harvest your vegetables.

Although the nutrients in the soak water have been leached from the seeds, the tremendous multiplication of nutrients occurring in the seeds as they are sprouted more than compensates for this loss.

Another option is to avoid the loss of nutrients by osmosis into the soak water by utilizing only enough water in presoaking the seeds so that all the water is absorbed into the seeds.

However, we do use the soak water when dried beans are soaked prior to cooking, which may seem inconsistent. Some authorities do advocate discarding this water also. But the soak water from the beans, if used, would be used in the preparation of the cooked beans.

There may be some validity to the suggestions to use the soak water by-product of the sprouting operation by mixing with other foods, especially if you are using cooked foods, such as soups or casseroles.

However, it seems to me that there is a basic difference in these two situations. If the bean soak water is discarded, there go a plethora of vitamins and minerals which have leached into the water! But, in the case of the soak water from the sprouts, the loss is adequately replaced and multiplied during the sprouting process.

As previously indicated, there is some disagreement as to whether or not to discard the water in which beans are soaked (usually overnight). Advocates of discarding the bean soak water say that although you will be discarding some nutrients, you will also be discarding many of the oligosaccharides that cause flatulence.

Those who advocate cooking the beans in the soak water believe that the marked and complex chemical changes in composition which occur in the beans as a result of hydration and soaking (the process described by Drs. Mayer and Poljakoff-Mayber—referred to previously) are also accompanied by alteration of the nature of the breakdown products, from which new materials are synthesized.

I have experimented with using and discarding the soak water, and have noticed no problem with flatulence when the soak water is used in cooking the beans; in fact, there doesn't seem to be any difference at all.

I am a good subject for this experiment, because for many years I was unable to tolerate legumes, either cooked or sprouted, because all legumes, even lentils, caused me distress. I eliminated legumes from my diet completely for about six months, and then restored them slowly and carefully. Now I use legumes (cooked or sprouted) occasionally, in moderate amounts, with no problem of flatulence.

You may decide to experiment with both methods—that is, using or discarding the soak water. I don't believe either method will affect your health and well-being. In fact, I doubt that you will notice any difference. I will welcome comments and reports as to the results of your experiments.

## 4.6 Avoiding Sprouting Problems

1. Start with the easiest to sprout: alfalfa, sunflower seeds, mung beans, azuki beans and lentils.

2. I have found it best to use sunflower seeds as soon as possible after a very short sprout appears; they tend to deteriorate rapidly.
3. Soybean sprouts are highest in food value, so try to eventually progress to sprouting them. Some people enjoy raw sprouted soy beans; others reject their taste in the raw state, but enjoy them cooked. Soy beans require far less cooking after they are sprouted. It is difficult to successfully sprout soy beans or grains in a jar; more sophisticated equipment is advisable, such as described later in this lesson.
4. Be sure to use new seeds with high germination values; old seeds or beans will become moldy or even rot during the sprouting.
5. Use distilled water for soaking. Usually, tap water may be used for rinsing, but if your tap water is high in chemicals, it may cause problems with sprouting, in which case, use distilled water for rinsing.
6. Spoilage may be caused by soaking too long. Usually six hours is long enough for seeds. If you are having problems, try sprouting seeds (such as alfalfa and sunflower) without the pre-soaking, or a very short (two or three hours) pre-soaking period. Dried beans (soy, mung, azuki) usually require pre-soaking, as much as eight to ten hours.
7. If you are having problems, try more frequent rinsing—in cool weather, two or three times daily should be enough, but four times daily may be required in warm weather. Be sure the drainage is good. If sprouting in a jar, be sure to maintain in a slanting position.

## 4.7 Sprouters

There are many other types of sprouters—some, makeshift but efficient (a bowl with a plate to cover and drain—instructions later) and some more sophisticated. I have an excellent sprouter which was made out of a clear plastic shoe box with an opaque cover. For draining, six 3/16" holes were drilled along one bottom end, a screen was cemented over them (inside the box); and ten larger holes (1/4" diameter) were drilled in the lid, along the sides. A small piece of wood is used in propping up the end without the holes and screen, when draining. The alfalfa and mung bean sprouts grow straight up and beautiful, instead of tangling inside a jar.

Health food stores have two quart sprouting jars available with stainless steel mesh screens in plastic screw tops which, of course, do not rust.

I also have a decorative, sprouting sphere called "Little Green Acre," which the folder says "provides light, humidity and air circulation in balanced harmony for trouble-free sprouting, and is specifically designed to utilize those light rays in the spectrum which enhance sprout growth." I do find it superior in many respects to other sprouting methods, but it is expensive, and you can do quite well sprouting alfalfa, sunflower seeds, azuki beans, mung beans and lentils in a jar. You may find your sprouts do better in the two quart wide-mouthed jar with plastic screw top and stainless steel screen, rather than the one quart Mason jar. The sphere does prevent souring of the more difficult to sprout soy beans and grains, and does not require as much attention—rinsing and changing the water in the base just once a day.

Regarding the garish color, mine is half ruby red (top half) and half purple. When I bought mine (introductory price at a Vegetarian Society Convention), it was also available in ruby red and green.

This sprouter produces a generous harvest of beautiful, straight-up green-leaved alfalfa sprouts, which can be harvested gradually, if desired. It is excellent for all varieties of sprouts.

Another excellent sprouter is the "Kitchen Garden Sprouter." It is ten inches in diameter and two and one-half inches deep. Water flows through the bottom as the sprouts are rinsed. It has a removable divided tray to make four different compartments for sprouting different seeds simultaneously without mixing.

## 4.8 Instructions for Sprouting in a Bowl

After soaking and draining the seeds, put them in a bowl, fill the bowl with water from the tap, cover with a plate and invert and drain. Allow the bowl to stand with the dish on top to keep the seeds at high humidity, but the plate should not fit so tightly that there is no air circulation.

Fill the bowl with water and drain two to four times daily. For better bottom drainage, try inserting a strainer or colander in the bowl.

Another bowl method is the use of a clay bowl in a pan of water. The clay bowl (or flower pot) absorbs enough water to keep the sprouts moist but not wet.

Some people use these bowl methods very successfully, others prefer more sophisticated sprouters.

## 4.9 Sprouting in Sand or Soil

Sprouts can also be grown in sand or soil. Sunflower seeds and buckwheat are especially recommended for this use. Plant in boxes or in the garden, allow to grow to about two to three inches tall, and snip off the green leaves for the salad. Soy beans, being subject to spoilage when sprouted the usual way, will obviously do better when sprouted in sand or soil.

[Home](#) > [Lesson 26 - Preparing And Serving Foods For Best Nourishment, Part I](#) > 5. Questions & Answers

## 5. Questions & Answers

**I have heard that blended salads have the advantage of enabling the consumption of greater amounts of green vegetables than would be possible if eaten whole. If one eats a regular raw salad, and an additional amount of blended salad, would you still object to the use of the blended salad?**

If there is no dental problem (or other problem involving the use of whole raw foods), there is no reason why all the salad desirable or necessary cannot be eaten as intended by Nature. When one has a feeling of surfeit (or, preferably, before such a feeling) after eating salad or any food, he should stop eating, not force more food into his body by "drinking" it. The use of blended salads often results in bombarding the digestive system with more bulk than can be comfortably or efficiently handled. Blending foods does not result in making them easier to digest. It does bypass the necessity for chewing, but the food arrives in the stomach without sufficient insalivation and without any signals for the secretion of the necessary gastric enzymes and digestive juices.

Even though I personally experienced serious digestion problems, relieved by a 29-day fast in 1967, today I eat mountains of raw salad and experience no problems as a result. When my body signals I have had enough, I stop eating. I have experimented with the use of additional blended salads, with negative results—cramps and discomfort. Even if overt symptoms do not occur as a result of "stuffing" with blended salads, future problems may be incubating. Enjoy your salads in their most appetizing and healthful form—whole, succulent and delicious.

**Why do you object to the use of hydroponic vegetables, and yet you approve the use of sprouts, which are also usually grown without soil or sunshine?**

It is true that sprouts are also grown without soil or sunshine, but they are harvested before there is a necessity for the nutrients provided by the soil or sunshine.

If seeds are grown beyond the sprout stage (to maturity or near-maturity), it becomes necessary to provide such nutrients. Hydroponic vegetables are provided with these nutrients through the use of chemicals added to the water in which they are grown.

### **How much dried fruit should be used as part of the regular Hygienic diet?**

Most dried fruit is very sweet. Such concentrated sweets should be used sparingly. Fresh whole fruit is better food, and much more acceptable to the organism, especially in warm weather. In seasons when fresh fruit is not plentiful, or in cold weather when one may feel the need for some more concentrated food, dried fruit may be used in slightly greater quantities. We never use dried fruit more than once in the same day, sometimes not at all. A reasonable amount (used with fresh fruit and lettuce and/or celery at a fruit meal) would be six to eight medium dates, three to five medium figs, four to six medium soaked apricots, two or three tablespoons of raisins, etc. If occasionally used with salad only and no fresh fruit, the quantities could be increased to about half again as much, if well tolerated. Overeating of dried fruit can bring on symptoms of a cold.

### **If one never gets beyond a "transitional" food program, can improved health be expected?**

Usually a transitional food program (eating less and eliminating all or most animal products and all junk foods, and utilizing a large percentage of uncooked food) will result in some health improvement, but, after a certain plateau is reached, no further progress can be expected unless further improvements are initiated. If one expects significant health improvement, significant and continuing progress toward true Hygienic living is necessary. However, if a transitional food program is accompanied by a regular, vigorous exercise program, and attention to the other facets of Hygienic living (unpolluted air; pure water; adequate rest and sleep; sun baths and air baths; mental and emotional poise; pleasant and secure environment; creative, useful, rewarding activity; meaningful relationships with other people; personal control and self-mastery; recreational activity; comfortable temperature; natural light; moderation in all activities; and dealing with illness by rest and abstinence from food, rather than the use of drugs and treatments) much greater progress toward optimal health can be achieved.

If serious problems exist, it is highly inadvisable to indulge in any compromise to true Hygienic living. An impaired organism should be offered only those foods which will provide maximum nutritional value in return for the work that must be performed in processing these foods.

### **Can people with conditions such as arthritis or high blood pressure be "cured" by changing to a strict Hygienic food program, using mostly raw food?**

Hygienists do not believe there are any "cures"—Hygienists merely assist the body to heal itself. Most people who are really in trouble must start out with a, therapeutic fast (usually fourteen to thirty days). Pathological conditions may sometimes respond to the change in diet, along with a regular, vigorous exercise program and other changes in lifestyle, provided drugs are not used. However, it may take a long time before any progress is observed. If the pathologies are serious and aggravated, the changes in diet and lifestyle will not accomplish the desired results within any reasonable length of time, if at all.

## **Article #1: Well, You Wanted To Know By V.V. Vetrano, B.S., D.C.**

### **Are there any recommendations for variations in summer and winter diets?**

Summer and winter diets must of necessity be slightly different because of the different varieties of fruits and vegetables that are available during these seasons. There are more varieties of fruit in summer than in winter. In the summer, one can rely solely on fresh fruit for carbohydrates whereas in the wintertime it may be necessary to use some dried fruit. In very cold climates one may increase the protein intake as protein has a tendency to cause more body heat to be manufactured thus keeping the person warm. Carbohydrates and fats also help produce more body heat but not to the extent as do protein foods.

### **What about dried foods and their needed soaking time?**

Unsulfered dry fruits are good foods and may be eaten in the dry state, soaked or slightly rehydrated. However, when fresh fruits are available they should be used in preference to the dried.

To soak dried fruits, use distilled water only. Place them in a bowl rather than in a jar or glass and put only enough water for the fruit to soak up so there will be very little remaining when the fruit is ready to eat. Usually eight to twelve hours will be adequate soaking time for most dried fruits. Actually, you can suit yourself and stop the process by putting them in the refrigerator and by controlling the amount of water you place on them. If you like them very soft, then use a lot of water. If you prefer them a little more firm, then use less water.

I prefer a method I devised myself. Not liking the tasteless water left when soaking fruits the ordinary way, nor the tasteless fruit after it absorbed water, I decided to just barely rehydrate the fruit. First, wash the fruit, then rinse it in distilled water. Next, place the fruit one layer thick on a flat plate or tray with about one eighth of an inch of distilled water in it. Cover to keep the fruit damp. Turn the fruit occasionally when the top looks dry. In about two hours the fruit is a delicious chewy soft consistency-not too soggy nor too hard. I think fruits rehydrated in this manner are much more savory than the soggy mushy tasteless mass that they become when completely soaked. If you prefer more softness add more water and let them stand longer. Turn the fruit approximately every half hour so it can soak up a little more water. With this method no sugar is lost into the water, as the water is all consumed by the fruit, none being left over to sap out the sweetness and nutrients. If you like delicious chewiness, try rehydrating your fruits in this manner instead of soaking.

## **Article #2: Some Fundamentals Of Food And Feeding By Ian Fowler**

### **What to Eat**

What to eat? Food! Fresh food! Natural foods. But what are natural foods? Cow's milk, honey, polar bear liver? No! Natural foods are not only foods unchanged by artifice but foods natural to man, that is, "natural" in the same sense as "grass is natural food for cows." Ideally our food should be palatable, unprocessed, uncooked and uncontaminated with pollutants, synthetic flavors, condiments, dyes, pesticides, preservatives, heavy metals, nitrates, plasticizers, etc. Our food should consist largely of raw fruit and vegetables, that is, food which is chemically and physically constituted in accord with our design or the "way we work best." Evidence directly implicating refined carbohydrate food in the development of Western patterns of disease is now substantial and cogent. In particular a diet rich in refined carbohydrates is almost certainly a significant causative factor in appendicitis, varicose veins, diverticulosis, bowel cancer, coronary heart disease, acne, diabetes, obesity, gallstones and piles.

Food is essentially composed of fiber, nutrients, flavor substances, water and poisons. The sugar-coated drug of a physician may be composed of the same classes of substances as may tea, coffee, cocoa and medicinal herbs, but we can hardly glorify them as foods because the nature and quantity of poisons they contain detract greatly from their nutritional value. Even synthetic foods and cooked food containing all known nutrients will not support life over successive generations. Animals that only consume such food become progressively deformed and infertile with each generation. Such food has understandably been called foodless food. Food is more than the sum of its constituents, for those are determined by destructive analytical techniques.

We should try to consume mostly living food that contains as little poison as possible. All food contains both artificial and natural poisons. So don't be discouraged if you discover that Brazil nuts contain oxalic acid. They do. Most fresh vegetable material does. But little of the oxalic acid from it is absorbed. However, some vegetable material contains "potent" poisons, e.g. "medicinal" herbs; these should be avoided. We should aim to meet our nutritional needs, while consuming as little poison as possible.

Some foods—indeed almost all foods—are claimed, by somebody, as having "therapeutic qualities" or "healing forces." If this were true, eating a mixed diet would constitute preventative treatment in the form of preemptive multiple cures! Indeed some "foods," such as tea, coffee, cocoa, peppermint, foxglove, belladonna, are used as stimulants, diuretics, etc., for they contain potent poisons (drugs) and represent primitive medicines. Caffeine, theophylline, theobromine, atropine, digitalis, are drugs which can be isolated from the above herbal sources and their administration is followed by physiological changes similar to those which follow the consumption of their parent herb.

No sophistry about "mineral balance" or "radiations" can make poisonous herbs nonpoisonous or anything other than injurious. Many people have double standards concerning drug use, e.g. marijuana is bad, alcohol is okay. Many people in the alternative health care fields have similar double standards. Tea and coffee are bad but peppermint and chamomile have "healing properties!" Similarly, some of the medical profession are reluctant to relinquish the hope that alcohol, coffee or tea. etc. have "curative" values.

To speak of food and to use food as "medicine" is to transfer to food all the misconceptions about drugs; to replace the notion "drugs can fix you up" with "food can fix you up." Food is material for use by the body, food does not do anything, it is done unto—digested, absorbed, metabolized. The consumption of a particular food or foods cannot substitute for the removal of poor foods from the diet or for the removal of non-dietary causes of disease such as cigarette smoking, lack of sleep, inactivity.

Advising the sick to change their diet is not necessarily advising diet therapy unless we think of

"therapy" as *everything* a sick person does in the hope of getting well. This understanding of "therapy" obscures important distinctions. For example a few years ago the most common medical dietary recommendation to those with diverticulosis was "avoid coarse foods-they irritate the bowels." Now that it is "proved" that lack of "coarse" foods "causes" diverticulosis, many physicians advise those with diverticulosis to "eat more coarse foods"—a complete about-face. The former dietary recommendation constituted "diet therapy," for the aim was to reduce symptoms rather than to provide needs or to remove causes and so, like all therapies, made things worse. The older dietary recommendations were therapeutic, the *Hygienic* dietary recommendations provide the needs of the body and omit unfavorable factors. A diet change (even a *Hygienic* one) understood as "food medicine" or "diet therapy," like drug therapy, blinds the sick and the well to the realization that the primary prerequisite for better health is the *removal of the extra-bodily causes of disease*. Applied to diet, this means that the avoidance of specific foods is usually more important to recovery than the eating of specific foods.

## Cooking

Overheard casual conversation:

"Doesn't poor old Mrs. Jones look unwell."

"Yes, the doctor says she's malnourished."

"Well, I suppose when you live alone you don't feel like cooking for yourself."

This illustrates a common misconception: that "good nutrition" and cooking go together. In general, cooking is undesirable. During cooking some nutrients are lost through oxidation, denaturation and leaching. In addition, some are converted to noxious substances, such as hydrocarbons and nitrosamines. Some nutrients are also converted to a variety of substances called secretagogues—substances so named because their presence in the stomach, even in minute amounts, evokes a vigorous secretion. Some secretagogues are partly broken-down food elements, for example, peptones (from protein). The upshot is that when cooked food is eaten, an untimely, excessive and inappropriately constituted (e.g. too acid) digestive juice is poured into the stomach and intestine.

The process of denaturation and splitting of food elements which occurs when food is cooked is often unwittingly called "predigestion." Cooking tends to "soften" the food, which encourages poor mastication and a whole train of consequences (see previously). Softened, denatured food moves slowly along and so tends to putrefy and ferment readily, especially if it is also refined and concentrated and not accompanied by a substantial amount of raw food. Cooking also tends to dehydrate the food, hence its consumption is frequently accompanied by thirst. This leads to drinking with meals and the drink is usually tea or sometimes fruit juice, which is frequently "incompatible" with the cooked food. Many popular methods of cooking, for example, boiling vegetables, result in the addition of aluminum from the pot and fluoride from the water. It has yet to be demonstrated that either of these elements is constructively involved in cellular life processes. Their, poisonous nature has been demonstrated repeatedly. Cooking also "drives off," leaches and destroys the flavor substances and organic salts, hence encouraging:—

1. the consumption of foods that would be distasteful if eaten raw;
2. the addition of salt, condiments, monosodium glutamate, etc., to "add flavor."

It is conceivable that a particular raw food diet that is nutritionally inadequate may be improved by addition of certain cooked foods. For instance, a protein-deficient raw food diet may be improved by adding cooked meat or egg yolk. But an adequate and suitable raw food diet may be preferable.

## Condiments

These tend to denature and precipitate enzymes and proteins, rendering enzymes ineffective and protein less digestible. Condiments are irritants which occasion an abnormal protective secretion of fluid and mucus instead of normal digestive fluids. Constant use of condiments leads to secretory impairment and

insensitivity to flavor substances. So those who use condiments regularly, or smoke, or drink alcohol, cannot perceive the flavor nuances of raw salads and many fruits. So, commonly, raw food is called, "tasteless herbage" or "rabbit food"—unless that "rabbit food" is mutilated as coleslaw and/or polluted with oil, salt and vinegar—the very things that have led in part to the sensory deterioration.

Common salt (sodium chloride) is perhaps the most frequently used condiment. In natural foods sodium and chloride ions are present in low concentrations and are avidly and easily absorbed.

Providing the kidneys are in reasonable condition, they rapidly excrete all salt added to food. However, chronic intake of added salt leads to impaired ability to excrete it, with consequent fluid retention. Table salt is also implicated in the development of some forms of "high blood pressure." In short, our so-called "mineral metabolism" works best on low intakes of sodium and chloride; so low, in fact, that a deficiency of these elements cannot be produced simply by feeding natural foods, no matter how little sodium and chloride they contain. Indeed if you develop kidney failure, liver failure, heart failure, or high blood pressure, a low-salt diet is medically recommended. Too late. Don't wait; omit salt from your diet now.

[Home](#) > [Lesson 26 - Preparing And Serving Foods For Best Nourishment, Part I](#) > Article #3: Vegetable Salads By Dr. Herbert M. Shelton

### **Article #3: Vegetable Salads By Dr. Herbert M. Shelton**

A large raw vegetable salad with each dinner is one of the most important elements of the diet. As a preventive of disease, it is far superior to all the vaccines and serums ever devised. Salad eating, at least in this country, is a recent innovation and had its origin among those who have been dubbed food faddists. The addition of a suitable salad to a meal always improves the nutritional value of the meal.

At the turn of the century cooking was much worse than now and the diet more gross-flesh, bread and potatoes or beans three times a day, with an assortment of side dishes, cakes, pies, etc., that would have made a meal for a 600-pound boar, all jumbled together in the most abominable combinations. It was an era when a flesh, bread and potato diet with such accessory foods as butter, cream, mayonnaise, sugar and sweet desserts were the most common reliance of the people. Fresh fruits and vegetables were scarce in the diet.

At that time the *medical* profession was horrified at the thought of eating uncooked fruits and vegetables. There were germs on them! "There are typhoid germs on all uncooked vegetables." But under the leadership of the "cranks," "faddists" and "quacks" the people took to eating these raw foods, and as the fresh foods entered the diet the germs vanished. No typhoid resulted from eating these germ-laden foods. Today, even the most bacteriophobic physicians eat these foods uncooked, the only food they refuse to eat without first heat-sterilizing is milk. (It also supposedly contains typhoid and tubercular germs.)

Although popular eating is less gross than formerly, people still overeat. They have relieved their stomachs and bowels to some extent but have thrown the burden on the liver, pancreas and ductless glands. Today the people are eating far more raw (uncooked) fruits and vegetables. Lettuce, cucumbers, celery, apples, strawberries, citrus fruits, etc., are raised in enormous quantities and shipped by trainloads to all parts of the country. Trainloads of lettuce are now raised where wheelbarrow-loads were formerly raised.

Until well within the lifetime of the author the medical profession advised never to eat "raw" fruits and vegetables because of the germs they carried. Not until it was discovered that raw fruits and vegetables

were the best sources of vitamins did they cease to warn against the germ-laden uncooked fruits and vegetables. (And this discovery came only after the profession was forced to recognize that people were getting well on diets of uncooked fruits and vegetables.) Indeed, they are still issuing the old warning when one goes into Mexico, India, China and elsewhere.

For physicians to have told their patients to accompany their beefsteak with a large combination salad of uncooked, non-starchy vegetables would have subjected them to ridicule. It would have been too easy for the people to trace the advice to its source in the hated diets of the faddists. So, they retired to their laboratories and came up with the *discovery* (the faddists had beaten them to the discovery) that the virtues of such a meal are due to the vitamin content of uncooked foods.

At those mutual admiration gatherings of physicians, called conventions, much is said, between smoking and drinking bouts, about diet, but in practice, the subject is avoided like the plague. It is a safe estimate that no less than 90% of the *medical* profession is giving no attention to diet, other than to ape popular sentiment on the subject. Many of them "believe in diet," but, as with the weather, they "do nothing about it." Every day the sick tell me that their physicians have advised them to eat what they please—that food has nothing to do with sickness.

One can listen to a physician talk loud and learnedly about vitamins, amino acids, food blends, calories, etc., and easily become persuaded that he knows what he is talking about. This is a mistake. The garrulousness of the profession is an acquired habit in the effort to see how much they can say about a subject of which they know nothing. Whole libraries of technical literature bear witness to their success.

The present-day hospital is a chuck-house, overfeeding its inmates on the same kinds of "good nourishing foods" that filled the hospitals in our grandfather's day. In these institutions there is no "newer knowledge of nutrition." Feeding a person who is said to be starving on such things as gelatin, alcohol, beef, tea, puddings, white bread, canned fruits and vegetables, pasteurized milk and such is a sure way of guaranteeing that the starvation shall be continued and accentuated.

To supplement a diet of this kind with vitamin pills and expect the patient to be well-nourished is the height of the ridiculous. Sooner or later the misled people are going to discover that vitamin pills are not satisfactory substitutes for uncooked fruits and vegetables. The medical profession resisted the effort to popularize the uncooked diet and science came forth with vitamin pills as a substitute, but the results of the pills have not been satisfactory. *Vitamins should come from the orchard and garden, not from the drug store.*

Nature turns out her products in a state of physiological balance and when we eat our foods as she produces them, they are not sources of trouble. But when we extract portions of her products, as when sugar is extracted from cane or beet or white flour is extracted from wheat, we eat an artificial product that is out of balance, lacking in many of the essentials of nutrition. The remedy for such a state of affairs is to eat whole, that is, unprocessed, unrefined and uncooked foods grown on fertile soil.

Vegetarianism comes in for much criticism and condemnation from the medical profession, which knows nothing about the subject of diet. When vegetarianism is defined as a system of diet that excludes flesh and the matter is allowed to rest there, with no well-defined rational or scientific adjustments of foods to the needs of the well and the sick, it can and will turn in many dietetic failures. When commercialism is permitted to force upon vegetarians a decided cereal bias, so that grains are prepared in many different ways to appeal to the palates of vegetarians, the vegetarian diet becomes decidedly unwholesome. Fortunately, in more recent years vegetarians have taken more avidly to uncooked nonstarchy vegetables and to fresh fruits. Among the health-conscious vegetarians, at least, better eating practices are in vogue.

A salad of uncooked, non-starchy vegetables should accompany every protein and every starch meal. The common practice of eating shrimp salad, potato salad and similar salads will not suffice. Indeed, such dishes hardly merit the name salad. The salad should consist of such foods as lettuce, celery, cucumbers, green and red peppers (the nonpungent varieties), cabbage, tomatoes and other non-starchy

vegetables. These foods should be served fresh and without salt, vinegar, olive oil, mayonnaise or dressings of any kind. Such "foods" are not recommended for salads nor to be eaten in any other way. Tomatoes should form part of the salad only when starches are not part of the meal.

To assure a plentiful supply of minerals and vitamins, a large salad, as suggested above, should accompany each protein and each carbohydrate meal. The customary salad consisting of two leaves of wilted lettuce and a slice of half-ripe tomato, topped off with a radish or pickled olive and a spoonful of greasy foul-tasting salad dressing, is not only unwholesome but does not meet the vitamin and mineral needs of a canary. A salad should be part of the most enjoyable food of a meal and will be if proper choices of salad materials are made.

[Home](#) > [Lesson 26 - Preparing And Serving Foods For Best Nourishment, Part I](#) > Article #4: Hypoalkalinity By Dr. Herbert M. Shelton

#### **Article #4: Hypoalkalinity By Dr. Herbert M. Shelton**

Acidosis is the term misapplied to a lessened alkalinity of the body fluids. The fluids of the body are normally slightly alkaline. A lowering of the alkalinity of these fluids is more properly termed hypoalkalinity. Acidosis or hypoalkalinity is defined as a condition characterized by a deficiency of fixed alkalies in the body, which leads to an increased production of ammonia in the urine and a high acidity.

Acidosis is not acid blood, for the blood never becomes acid during life. An alkaline blood and lymph is necessary to life and health and for the blood to even reach the point of neutrality would cause speedy death.

The normal ratio between the alkalies and acids of the body is approximately 80 to 20—80% alkali and 20% acid. This proportion is maintained in balance by the so-called "buffer salts"—sodium, potassium, calcium and magnesium—from which either side may draw as need arises. When this "buffer" or "balance wheel" is in normal order any excess of acids in the body is promptly neutralized. It is only when there is a deficiency of these salts that troubles may arise. A shortening of the relationship between these is wrongly termed acidosis.

The body will not tolerate any free acid for a minute, except in the stomach during the process of digestion. All acids are instantly "bound," by being combined with alkalies, to render them harmless. The body makes use of every resource at its command to preserve its alkalinity for the reason that its cells can thrive only in an alkaline medium and cannot possibly thrive in an acid medium.

Since we supply acids and alkalies to our bodies through food, the matter of a balance between acid foods and alkali or base foods is important. If an excessive amount of acid food is eaten, the blood is forced to draw upon its alkaline reserve, its "buffer salts," in order to maintain its normal alkalinity. When we have taken more acid into the body than we can "bind" without sacrificing some of the bases of the tissues, blood alkalinity falls below the normal level and we have hypoalkalinity or acidosis.

Every food eaten leaves behind it an ash after it has been used by the body. The ash is either acid or alkaline. Eating too much acid-ash food, or eating it over long periods of time, results in storing acid-ash in the cells and in depleting the body of its alkaline reserve.

Acid-ash foods are all meats, eggs, cheese, milk (in adults), all cereals and cereal products, legumes (except in the green state), nuts, and all denatured foods of all kinds. Denatured foods have been robbed of their bases.

The alkaline-ash foods are fruits (except cranberries, prunes and some plums), all green vegetables and milk (in infants). Fats and oils are classed as neutral foods.

Severe acidosis may be produced experimentally by deficient diets, but such severe states are seldom met with in life, except in famine. Maignon has repeatedly shown that an exclusive protein diet is positively toxic even in the carnivora. Whipple, Slyke, Birkner, and Berg have shown the same thing.

The medical administration of acids, such as salicylic acid (often in aspirin), benzoic acid, boric acid, sulphuric acid, etc., leads to a dangerous loss of bases, for these acids can be rendered harmless and subsequently eliminated only after being combined with alkaline elements. Hydrochloric acid, prescribed by physicians in supposed gastric hypoacidity, also leaches the body of its bases and aids in producing acidosis.

Free acetic acid, as found in vinegar, if consumed in quantities, may lead to symptoms of acid poisoning. It is even more injurious to health than alcohol. The body is called upon to sacrifice its bases to neutralize the acid, while it has a particularly destructive effect upon the red corpuscles and may produce anemia.

A diet poor in bases, or food that has been robbed of its bases, has the same deleterious effects. The meat diet, as used in civilized countries, is of this type. An exclusive muscle-meat diet, when fed to dogs, will not maintain health and growth. If dogs are fed on meat from which the juices have been expressed, "emaciation ensues after a time, toxic symptoms set in, death speedily follows, and post-mortem examination shows in the skeleton changes characteristic of osteomalacia and osteoporosis." (Osteomalacia is softening of the bones; Osteoporosis is the rarefication—decrease in density—of bone due to enlargement of its cavities or the formation of new spaces.)

[Home](#) > [Lesson 26 - Preparing And Serving Foods For Best Nourishment, Part I](#) > Article #5: Sprouts And Sprouting by H. Jay Dinshah

## **Article #5: Sprouts And Sprouting by H. Jay Dinshah**

I was very interested to read the article by Dr. Vetrano on sprouts in the September issue of the *Hygienic Review*, and there is much "food for thought" in it. However, I cannot agree with the conclusions drawn, apparently largely based on the letter from "N.P." These are totally inconsistent with the facts given in Ford Heritage's book that he cites as his authority.

On page 1 of the book *Composition & Facts About Foods*, Heritage specifically points out that dashes given in place of numbers in his tables do not mean zero nutriment contents: "In some cases information was not available at the time of assembling this material. This is indicated in the tables by a dash (-). It is hoped that such missing information may be forthcoming at a future time." N.P. has totally misquoted these in his letter, rendering the dashes instead, as "0"; this is not as they appear in the book, for in each and every case cited (pages 26-27, soybeans) Heritage lists the missing ingredients with a dash (-), meaning simply that such information was not available to him. This is not surprising, with the interest in sprouts being a fairly recent phenomenon, and with not much of this interest in the orthodox circles from which Heritage drew his information. Clearly, then, the supposedly vanished elements have not "gone anywhere"; they simply have been unlisted due to lack of that specific information.

But let us look at the supposed "loss of Vitamin B" which Dr. Vetrano has mentioned. I refer exclusively to Heritage's tables, these being the sole expert or factual source cited by either Dr. Vetrano or N.P. We must realize that in the process of sprouting, the dried out (and in that state, virtually inedible) seed has been returned to a viable condition, through restoration of its lost moisture. In the specific case of

soybeans, some additional water has been absorbed (as it naturally would be from damp earth), to reconstitute the seed to somewhat more than the percentage of water found in the original fresh soybean. The water content percentages are: fresh, 60.2%; dried, 10.0%; sprouts, 86.5%. This water content is the missing key that has eluded both Dr. Vetrano and N.P., and led them to jump to faulty conclusions about "missing vitamins."

If we began with (for example) a single ounce of dried soybeans (seeds), and then reconstituted the water through soaking and sprouting, we would then have a total food weight of approximately six ounces of soy sprouts. The dry (non-water) material present would originally have been 90% of one ounce, or .9 oz. It would still remain roughly 9 oz., but would now be distributed throughout six ounces of food, the balance being the added water content. Percentagewise, all nutrients but water will have been cut by a factor of 6:1, but they have not "gone anywhere"; they are still there as before. Dry material would now be about 14% of the total, compared with 90% of the old dry weight. Using the factor of 6:1 as a convenient round figure, we proceed.

About the actual weight of fat has been burned up, as "fuel" for the new life; this is of insignificant nutritional content for the purposes of this discussion. The calcium content, which was 226, should now have dropped to about 38 (mgs. per 100 gm. portion); but we note it is listed by Heritage as 48. Clearly, we have no net loss of calcium. There is some loss of iron and phosphorus noted in the chart, the iron content being slightly less than expected, and the phosphorus about 2/3 of what could reasonably be expected from the 6:1 dilution. So we may have lost 1/3 of the phosphorus.

Let's look at the feared Vitamin B losses. This is very revealing: it is exactly the opposite! Thiamine (B-1) was 1.10 mgs. per 100 grams; now diluted at 6:1 with water, it must be around .18, but is in fact listed at .23, a gain of over a quarter of the original amount present. Riboflavin (B-2) is listed originally (dry state) as .31; in 6:1 dilution with water it should be .05. But it has a shot up to .20, indicating *four times* the net amount of riboflavin as compared to the original amount in the dry 1 oz. of seed.

*Percentagewise* the concentration in the 6 oz. of food has dropped to 2/3 of the former content, but we nevertheless have a total amount of Vitamin B-2 that is 400% of the original amount.

Niacin is listed at 2.2 mgs. originally, which would theoretically be diluted by sprouting to less than .4 mgs. But again the reverse is true, for the figure is .8 for the 6:1 water-diluted sprouts, showing a doubling of total niacin present in the six ounces of sprouts, as compared with original content in the 1 ounce of seeds. Ascorbic acid (Vitamin C) content is unavailable in Heritage's charts, for the dry state, but Dr. Vetrano admits that this is increased. It is not, however, the "only vitamin increased." The Vitamin A content was originally given as 80 international units per 100 grams edible portion. In the sprouts it is still 80 units per 100 gms., but remember that we now have six ounces of sprouts, thus we have SIX TIMES the original net international units of Vitamin A; even though the percentage would still be identical to the former percentage, we have nonetheless six times the available quantity of nourishment in regard to this important vitamin.

I hasten to add that these additional net amounts of vitamins did not have to "come from somewhere" outside the seed; it can easily be understood as a matter of natural processes of rearranging molecules and compounds, synthesizing relatively nonuseful raw materials into more useful (for human nutrition) materials. The same thing occurs within the intestines of humans, producing B-12, for instance.

Protein content must also be taken in the light of the same 6:1 formula, allowing for the great increase in water content to bring the seed to its viable and edible condition. Thus, we had a figure of 34.1% dry protein, now 6.2% for the sprouted soybean. Yet, we see no complaints that most of our protein has vanished into thin air, or been leached out through osmosis. It has gone nowhere at all; it is simply comparing the same amount to a percentage of 1 oz. or a percentage of 6 oz. of total food. An analogy of this apparent paradox of "vanishing nutrients" is seen among the legumes as well. Dried peas and beans are often cited as having enormous protein contents, based upon hasty scanning of charts listing *dry* weight. This makes them a very good buy, dollar wise. But when reconstituted with water to make them edible, of course, the content of protein is fractionated along with everything else, rendering them

a fairly good source of protein (percentagewise), but certainly no "super-food" in protein content. Similarly, dry seeds can be a good value, as you add water yourself; if you buy presprouted seeds, you pay for convenience, as 5/6 of what you buy is water. Perhaps we shouldn't mind this, as much of the *Natural Hygienic* food (such as fruits and salad items) is largely water anyway.

In regard to overpricing among health-food sources of seeds, it should be noted that the cheap open-market seeds sold for flour-making (for example) often are so stale they will not sprout at all, or at least have a high proportion of "dead" seeds. Freshness is very important; organic growing without sprays may also account for some of the additional cost. If N.P. can buy seeds at 1/5 the price in small quantities, which are *equal in quality* for sprouting purposes, we would be delighted to learn of his source. We do not sell them, but we do use them, and would be glad to save even more on sprouting.

We can see no major objection to Dr. Vetrano's method of sprouting seeds in white sand, but it should be noted that this would add nothing to the nutritional value of the sprouts either; the sand would merely act as a holder for the sprouts and the moisture; it might also be difficult to separate the grit from the sprouts. We feel the sprouter-jar method is cleaner in this respect, and see no drawback in having sprouts that are curled instead of straight. This probably comes about from tumbling in the jar, preventing the sprouts from consistently growing in the same direction. This would have nothing to do with nutrition.

So, to summarize: the vitamins do not "go anywhere"; they are manufactured by these busy little new lives from cruder materials within the seeds themselves, apparently. There is no vitamin loss in terms of net material available for human consumption, and it is a fallacy to use the dry material percentage of vitamins as a yardstick without allowing for the six-fold increase in water content. Allowing for this, there is a fair to tremendous increase in Vitamins A, B-1, B-2, niacin, and C, properly disregarding the specious dry seed percentage which is not available to us in that state. Otherwise, obviously you could say the same criticism of any natural food. One could take, say, bananas, dry them out, and say that the dry bananas are so much more nutritious than natural bananas. This ignores the fact that if you eat the dry food, you must then drink correspondingly greater amounts of water to supply your body's moisture needs, and you would then be right back where you started!

As we have noted, there is some loss of nutriment by osmosis if seeds are soaked. We have already experimented with utilizing only the proper amount of water in presoaking of seeds for sprouting, so that all the water is absorbed into the seeds. This would preclude any possibility of osmotic loss into the water, of any nutriment; and we are now advising fellow *Hygienists* to follow this simple precaution to avoid the possibility of such loss. We thank Dr. Vetrano for drawing our attention to this possibility, but this should satisfy that sole objection to the use of the sprouts.

Regarding N.P.'s objection to sprouts being grown "without any sunshine," this is simply not true of the better sprouting methods. Sprouts are generally grown in subdued light for the first 2 or 3 days, corresponding to the germination period in the earth; but it is advocated that they be placed in at least indirect sunlight (skylight) for the last day or so, and this is analogous to the new shoot peeping up through the earth. At this time, it turns green and begins the chlorophyll photosynthesis chemical reactions, exactly as any new plant would. I trust this will all help to dispel any fears that any fellow *Hygienists* may have about possible "vitamin losses" through sprouting. As we have shown, all vitamins cited experience a moderate to great increase through sprouting, in terms of amounts available for humans.

Editor's Notes: When harmony and cooperation are urgently needed for the advancement and good of *Natural Hygiene*, why should the leaders demonstrate contention and a lack of the poise stressed in the pedagogy of *Hygiene*? Why split hairs over the method of sprouting seeds?

Soy beans, being subject to spoilage, must obviously do better when sprouted over well-dampened sand. A method which lessens soaking and rinsing of seeds seems desirable. Since eye appeal is advocated in serving food, why not have straight, green, hearty-looking sprouts? Dr. Vetrano says the sand readily leaves the sprouts when water is poured over them, and if necessary, the sprouts are dipped up and down in the water for a moment. Until the method is tested, why not withhold contradiction and accept her

discovery?

In actual practice, much of the sprouting is done away from the light.

To compare bananas, which must be dried artificially, with beans, which are dry naturally in the ripening process, seems a poor analogy.

We can be thankful that a natural process makes food appropriated by cereal grass-eating animals, along with other seeds, acceptable to the human digestive system. But, while enjoying this fascinating bonus viand more or less frequently, we'll depend for our sustenance chiefly—added to fruits, nuts and non-sprouted seeds—on the broad leaves and other fresh green vegetables from the garden (organic, we hope), because of their free exposure to air, soil and sunlight.

What a marvelous full provision we have in the *Hygienists'* diet, unspoiled by cooking and processing.

Elegant simplicity!

[Home](#) > [Lesson 26 - Preparing And Serving Foods For Best Nourishment, Part I](#) > The Marvelous Avocado

## **The Marvelous Avocado**

*How to buy and ripen them. How to prepare, combine and service them. Important considerations as an item of diet.*

"The avocado is Nature's butter!" I've heard this comment from several lovers of this fine food. And many of them use it just as if it were butter, spreading it on cooked potatoes, bread and other foods. Needless to say, cooked foods are less wholesome in the diet than unfired foods. Also, avocado does not combine well with all foods. Digestive problems and poor health result from eating a rich food like avocado in incompatible combinations.

Yes, avocado does have a consistency much like butter and is far more wholesome than butter. But it should be thought of as a food in itself and not as a butter substitute.

Many Hygienists/Life Scientists are confused about how to combine avocado with other foods. Some food combining charts show it as both a fat and a protein while other charts show it as a fruit of a very special character, a fruit in a category by itself. Some Hygienists combine avocados with other fruits. We'll try to clear up this confusion.

## **How To Combine Avocados**

The avocado is made up of the same basic elements as nuts. Both contain a large amount of fat and protein. Even though both are technically fruits, we treat them differently and separately from other fruits because their dietetic character is determined by their heavy protein/fat content. Therefore, avocados should be treated like nuts in food combinations.

The main difference between avocados and nuts is that avocados are about 75 percent water and nuts contain very little water, only three to five percent. For example, let's compare the avocado with the pecan. Except for the difference in water content, these foods are almost identical in make-up. There are two other differences that are worth considering, too:

1. Avocado is alkaline in metabolic reaction and the pecan acid. As you may know, no more than 10 to 20 percent of your diet should be acid-forming foods such as nuts and seeds. The remaining 80 to 90 percent should be alkaline foods such as fresh fruits and vegetables. The more alkaline and

few acid foods in your diet, the better.

2. The avocado has a broader range of nutrients than does the pecan. We are very tempted to tell you the number of calories, percentage of fat and carbohydrates, grams of protein, milligrams of Vitamin C, etc. of these two foods. We have these figures at our fingertips in the USDA's book, *Composition of Foods* (Handbook No. 8). But Life Scientists eating an abundance of fresh whole fruits, vegetables and nuts don't need to get bogged down in figures. We get as much as we need of everything we need because we don't lose nutrients from cooking and otherwise processing our foods.

Despite its broader range of nutrients and its alkaline-forming character in the diet that make it preferable to nuts and seeds, avocado should not necessarily always be eaten in place of pecans and other nuts and seeds. It is good to eat a wide variety of foods over days, weeks and months. This assures a variety of nutrients as well as a more interesting diet.

We should eat nuts with green leafy vegetables, tomatoes, cucumbers and other nonstarchy raw veggies. The same is true for avocados. We should eat them with lettuce, celery and such non-sugar fruits as tomatoes, peppers, cucumbers, etc.

## **How Much And How Often Should You Eat Avocados?**

Avocados should not be eaten to excess because we would get too much fat and protein if we ate too many. One-half of one a day or one every two or three days is enough. They should be the only protein/fat food at the meal and the only protein meal of the day. It is not necessary for most people to eat a protein/fat meal every day. The high energy level and leanness that go along with a diet relatively low in fat and protein is desirable. However, we do require a small amount of the essential fatty acids that are abundant in avocados and nuts.

If you have nuts or seeds, three to four ounces is the most that should be eaten in a day. If you choose avocado, one average-size one is a reasonable serving portion. In fat and protein content, one medium avocado is equivalent to about one and a half to two ounces of nuts. Many people feel more satisfied after eating an avocado than such a small amount of nuts or seeds. This is very much in the avocado's favor because we are better off healthwise with less fat and protein in our diet and more sugar-containing fruits. We should get most of the energy (calories) we need from sugar-containing fruits, not from nuts, seeds or avocados. This is true even if you do heavy labor. Our fuel requirements are best met from carbohydrates, namely sugar-containing fruits.

## **The Economics Of Avocado Eating**

Avocados average about 69 cents each throughout their season, sometimes being a dollar each out of season (winter—December-February) and as little as 49 cents each at the height of the season. They are not the most economical food. Sunflower seeds are a much better buy. But I personally prefer avocados over nuts because taste and ultimate wholesomeness are my primary considerations in buying food.

## **How To Buy And Ripen Avocados**

If you buy avocados on a weekly basis it is best to buy hard green ones. They will become somewhat soft to the touch and dark colored when they're ripe. There will be no hard spots. They will ripen in about two to four days at room temperature. If too many become ripe at once, you may refrigerate them one to three days without much further ripening or deterioration. However, avocados do deteriorate rapidly once they've ripened. For this reason it isn't wise to buy avocados that have already ripened in the store unless you plan to eat them the day of purchase.

Good avocados have a consistent yellow-green color throughout. If part of the flesh has turned grey, black or brown, cut out those portions. If the taste isn't great, don't eat it. In time you will become an

expert at picking out good avocados and knowing how to ripen and store them.

## **Varieties Of Avocados**

We have been describing the Hass avocado, which is the most popular type on the market. But there are other varieties, none of which compare well with the Hass in flavor. The Fuerte variety is probably second best to Hass avocados. Bacon avocados are also sometimes available. Bacon and Fuerte avocados have smoother skins than the Hass, much less flavor, usually, and a higher water content and less fat and protein. For instance, Hass has about 75 percent water content and other varieties may have around 83 percent.

## **How To Prepare And Serve Avocados**

The avocado may be prepared and served in many ways. One of the favorite ways is to serve it on the half shell, spooning out the flesh. Just cut the avocado in half lengthwise, cutting around the pit. Then remove the pit with the point of your sharp knife.

Another method for serving avocado is to quarter it around the pit and then twist off the quarters and remove the pit from the final quarter in the same way it is removed from a half. Next remove the skin from each quarter. The sections may be served on a platter along with other salad vegetables, or they may be cubed into a cut-up salad. Many people make cut-up salads and simply spoon the flesh of the avocado out of half-shells into the salad bowl.

Yet others make guacamole with avocado by mashing it and possibly adding tomatoes. Or they make a dressing by blending it with tomatoes and other veggies. Guacamole and salad dressings made with condiments such as garlic, cayenne, onions, etc. are not wholesome because of the irritating and poisonous nature of these seasonings.

Avocados are becoming a part of the diet of many Americans. This is good, as the avocado is a delicious, creamy-textured fruit that provides wholesome nutrition. If you're not already an avid avo fan, try out this wonderful food!

### 1. Cooked Foods

#### 1.1 Cooking Impairs or Destroys Nutritional Value

In Section One of this subject, it was emphasized that shredding, grinding, blending, juicing and over-washing of foodstuffs impair their nutritional value. *Cooking, of course, is the most destructive process of all.*

When food is heated, all of the enzymes are destroyed. Very little, if any, Vitamin C can survive the process of cooking. Other vitamins and minerals are also impaired.

Amino acids (the building blocks of protein) are radically changed. The protein in raw nuts and seeds, and uncooked fruits and vegetables, are readily available to the body and are therefore said to be of high biological value. As the various stages of digestion occur, the long chains of amino acids are split for use by the body in synthesizing its own protein.

But when proteins have been cooked, or otherwise processed, they coagulate into enzyme-resistant linkages, so that cleavage by the body is inhibited and liberation of the amino acids for body use may not occur. This can result in putrefaction—decomposition of protein matter by micro-organisms, producing malodorous and toxic substances, evidenced by foul-smelling bowel movements.

The subject of the contraindications to the use of cooked food will be treated in greater depth in a future lesson.

#### 1.2 Deviations from the Ideal Hygienic Diet

At no time should we compromise the three major tenets of the Hygienic food program:

1. Whole foods are superior to fragmented and refined foods.
2. Raw foods are superior to cooked foods.
3. Plant foods are superior to animal foods.

Admittedly, because of various anatomical, physical (or emotional) weaknesses and defects, not everyone can adhere to the philosophical dietary ideal with complete success. (See "Hygienic

Considerations In The Selection of Foods" by Dr. Ralph C. Cinque, in the Supplementary Text Material section of this lesson.)

However, it is of major importance that the student first understand what constitutes an ideal diet—before he can be competent to make decisions about deviations from this ideal—either for himself or for others.

Realizing that many people may not be ready, or willing, to immediately embark on an all-raw food program, Lesson 27 includes recipes for more or less conservatively cooked foods.

Less harmful substitutes for conventional recipes are provided, to enable people who insist on using cooked foods to do it with the least possible destruction of nutritional value compatible with the desired result.

[Home](#) > [Lesson 27 - Preparing And Serving Foods For Best Nourishment, Part II](#) > 2. Preparation Of Cooked Foods

## **2. Preparation Of Cooked Foods**

### **2.1 Cooking at High Temperatures**

The general rule is: the higher the temperature, the greater the destruction of nutrients. However, cooking a long time at low heat causes more damage to food than quick-cooking by bringing water to the boiling point, then reducing the heat and steaming for ten minutes or so.

Pressure cooking, involving the highest temperatures, is the most destructive of nutrients, and should never be used.

### **2.2 Microwave Cooking**

Microwave cooking is a threat to humans because of leakage of the microwaves. People with pacemakers are warned to stay away from these appliances when they are in operation. This warning is necessary because of the danger of leakage.

Besides, it is not really known whether the microwave produces destructive changes in the food. And what's the rush? Most vegetables steam to a tasty, crisp-cooked state in ten minutes or less. Don't use microwave ovens.

A person who worked in a restaurant kitchen several years ago told me that someone came in one day to monitor the microwave ovens with a device that detected leakage and found one of them to be "leaking like a sieve" (as he put it). Of course no one knew how long it had been leaking like this, exposing the kitchen workers!

### **2.3 Charcoal Broiling**

A 1978 report from Dr. Arthur Upton, director of the National Cancer Institute, confirmed warnings against charcoal broiling. He cautioned that this may be a source of cancer-producing substances; charring of the surface of the food produces a tar fraction like the tar in cigarette smoke, and another dangerous substance is formed by breakdown of amino acids.

Dr. David Kriebel, research associate at Washington University in St. Louis, also warned against charcoal broiling in 1978. He said that heat applied from underneath and fat dripping into the coals

result in the formation of a known carcinogen—benzopyrene—which rises onto the surface of the meat.

## **2.4 Stir-Frying**

The advantage of stir-frying in a heavy skillet or wok is that the food is cooked only three to five minutes until crisp and tender. Usually this method works best for vegetables.

The disadvantage is that the oil is heated, and, while the oil is not maintained at the high temperatures used for French frying, it is still highly inadvisable to use heated fats.

I have sometimes successfully stir-fried some vegetables using water only, but it is tricky.

## **2.5 Steaming vs. Baking**

Steaming vegetables in as little water as possible only until tender-crisp (about five to ten minutes) preserves nutrients better than baking. Root vegetables can be steamed until the starch is dextrinized and the flesh is palatable, and will require longer cooking time (about 20 to 30 minutes).

Baked root vegetables require higher temperatures and longer cooking times, resulting in greater destruction of nutrients.

## **2.6 Cooking Fruit**

There is almost no excuse or reason for cooking fruit. I almost omitted the word "almost". There may be some exceptions—I can think of one. Plantains (similar to bananas) are fruits, and do require cooking, if you use them. They are ripe when very dark, and may be steamed or baked until the starch is dextrinized.

As for baked apples and cooked applesauce, it is a shame to cook good, organically grown apples. Commercial apples, however, are not much good raw or cooked. But it is possible that some extremely debilitated people may temporarily be unable to tolerate the raw fruit and therefore resort to cooked fruit.

Some people think they must cook dried fruit—not so! Buy untreated dried fruit and soak overnight or longer—it will be tender and palatable.

Dates, moist figs, dried bananas and dried apples require no soaking—they are much better and tastier without soaking. Dried raisins, prunes or cherries may be used either way. Dried apricots, peaches, pears and hard, dry figs should be soaked.

Saturating fruits with sugar and baking them into pies is a sacrilege.

## **2.7 Nuts**

Nuts should be eaten without any roasting, frying or other cooking. Cashews (not really nuts, and not really raw) may sometimes be used as a topping for casseroles. (See Eggplant Casserole recipe.)

Chestnuts (starchy protein) may be eaten raw, if not bitter, but are delicious roasted. If you prefer them that way, prepare them as follows: wash and discard those that float. With a sharp knife, make a slash along the flat side in each chestnut. Put in boiling water, boil five or six minutes. Bake in a covered dish for about 20 minutes at 375 to 400 degrees (or until skins are slightly browned). Both skins (the outside shell and the inside skin) can then be removed together, either by hand pressure, or by using a knife, usually leaving the nut whole and unbroken. Chestnuts may also be cooked or steamed until tender—this takes less time than roasting (baking)—perhaps about ten minutes.

## **2.8 Eat as Much Raw Food as Possible**

Cooking at any temperature destroys all the enzymes—they are inactivated by a temperature only a few degrees above body temperature.

Dr. Paul Kouchakoff, a Swiss researcher, found that a largely raw food diet offsets the adverse effects of cooked food, so as not to cause leukocytosis (an excessive number of white corpuscles in the blood). Most people can tolerate a diet of 80% raw food with 20% cooked food, as a transition diet (with the goal of eventually progressing to an all-raw food diet, or, at least, to less, and less cooked food). The critical temperatures at which most cooked foods become subject to production of this "pathological" reaction (leukocytosis) is 191 to 206 degrees.

## **2.9 "Cooking" at Low Temperatures**

There is a way to "cook" food and dextrinize starch without heating the food to these critical temperatures. Many years ago, before I knew about Natural Hygiene and the "no-breakfast plan" (or fruit only for breakfast), I used to prepare my breakfast the night before by putting wheat or rye berries, or wild rice kernels, in a wide-mouthed thermos, pouring boiling water over it, and quickly capping the thermos.

It is my understanding that this method produces a temperature of perhaps 150 degrees in the food, although it was always soft and fluffy and ready to eat the next morning. This method of preparation also neutralizes the phytic acid in the wheat and rye. (Phytic acid is antagonistic to calcium and other minerals, as pointed out previously.)

An article in *The Health Crusader* revived my memory of this practice. The article stated that this method could be used for brown rice by soaking it overnight, draining in the morning, then putting it in a wide-mouthed thermos, pouring boiling water (distilled), over it, and quickly capping the thermos. The rice will be soft and fluffy in time for the evening meal. Potatoes or yams or other vegetables can also be "cooked" in this same manner. Experimentation will determine the length of time necessary to tenderize the various vegetables.

## **2.10 Steaming**

The next best way to cook food is steaming. Most vegetables may be steamed unprepared, whole and uncut. Very large carrots may be cut in two or more pieces, rutabaga may be cut into medium-sized pieces.

I previously used a steam marvel (a stainless steel perforated platform inside the pot), but discontinued the practice for the same reason that I discontinued the use of all metal cookware. I use Corning ware for some purposes, but I prefer my tight-lidded, porcelain-enameled "Show pans".

The stainless steel steam marvel darkened the steaming water, so it was obvious that there was some leaching of tiny metal fractions.

Steam vegetables in a very small amount of water a very short time. This requires care and watchfulness, but the vegetables are not drenched with contaminated steam.

Dr. Vetrano agrees on this point. She says she does not use the steam marvel, or any rack, for several reasons. It tempts you to add more water than necessary, the water becomes steam, condenses on the lid and flows down over the vegetables anyway. Without the rack and all that water, the cooking juice tastes better and the vegetables taste better.

She suggests the use of three layers of the discarded outer leaves of lettuce to protect the vegetables from burning, in which case very little water will be necessary.

Steam just long enough to slightly tenderize without losing shape or color. (See Dr. Vetrano's article in

this lesson.)

## **2.11 Other Cooking Methods**

Other types of cooking, at higher temperatures, and for longer periods of time, are progressively more destructive and less advisable. However, some recipes will be included in this lesson for casseroles and other combinations that require such less advisable cooking methods, and are intended to serve only as replacements for even worse cooking practices, since many people will not be weaned away from conventional meals immediately, and require recipes other than those for simply prepared, lightly steamed vegetables.

In all cases, the least destructive method of preparation will be recommended, consistent with the preparation of tasty vegetarian meals which will be acceptable for transition meals, reluctant families, children, or entertaining.

## **2.12 Cooking Vessels**

Many years ago I discarded my aluminum "waterless cooking" pans, having been convinced that the leaching of aluminum fractions into the food was harmful. About eight years ago, I stopped using my stainless steel cook ware, having seen evidence that even stainless steel cookware leached metal fractions (as previously described in the use of a stainless steel steam marvel, and also confirmed by other reports).

I used Corning ware for a long time, finding it less than satisfactory, because the lids are riot tight enough. Now I am using "Show pans," a good quality of heavily enameled ware, with tight covers. These utensils spread heat quickly and evenly and hold the heat. Very little water is required, and a vapor seal forms between the edges of the pot and the cover. The oxidation is thus minimal and the vegetables are tenderized in a short time. Flavor is retained, and loss of vitamins and minerals is minimal.

It is my understanding that no leaching occurs in the use of glass, Corning ware, or enameled cookware. If enameled cookware is chipped, it should be discarded. Good quality enameled cookware is highly chip-resistant.

## **2.13 General Information About Cooking**

Leafy vegetables (or any vegetables) should never be cooked so long that they change color. Cook as short a time as possible, and serve immediately.

The practice of adding bicarbonate of soda to vegetables to preserve their green color destroys their food value and taste, impairs their digestibility, and is certainly not necessary.

Butter, cream or oil should never be added to vegetables while cooking—fats should never be cooked. If you must use them, add when serving. A small amount of butter is preferable, to oil. Better yet—try using a piece of avocado instead—it is tastier, and far superior nutritionally. Eggplant is an excellent and tasty vegetable, but requires extra care in preparation (see recipes). If very young and sweet, eggplant may be used raw. Use slices as a sandwich for tomatoes; sprouts, lettuce, or any other raw food.

If soups are used occasionally, they should be thick, not watery.

Potatoes, yams, salsify, rutabaga, kohlrabi, beets, carrots and parsnips may be steamed or baked. Steam whenever possible. Steaming is faster and preferable nutritionally, Steamed potatoes and other root vegetables retain more nutrients—because of lower heat and shorter cooking time. Scrub clean and steam in skins. The red color of steamed beets seeps into the steaming water unless cooked whole, with skin intact.

Baking sometimes produces a tastier product—my husband and I love baked potatoes and sometimes indulge ourselves. Baked carrots, parsnips and beets are also delicious, and may be indulged in occasionally.

Carrots, parsnips and beets sometimes spatter the oven, so a covered dish should be used. This also shortens the baking time. Select beets about two inches in diameter, or cut in half. These three vegetables will all bake in about thirty minutes or less, and are a delicious combination when used together. They have a special sweetness when baked.

For greater nutritional value, steam these vegetables, or eat carrots and beets raw (or grated, which some people find necessary, into salads. Any grating should be done *immediately* before eating). Young garden parsnips may also be eaten raw. If you like these vegetables baked, use occasionally as a special treat.

Potatoes may be baked in an open pan. Pierce white potatoes with a fork before baking. Bake without foil or any coating. Scrub well, and bake in open pan in 400 degree oven. Small potatoes take about 45 minutes, large ones one hour or longer. Baking time may be reduced by cutting potatoes in half.

Another "trick" for reducing baking time of white potatoes is to plunge them into very hot water for two or three minutes before baking. Bring water to boiling point and remove from heat before inserting potatoes. I would suggest reserving this method for use in emergencies only, when time is limited. If you need the potatoes sooner than they can be baked, it would be better to steam them instead.

Always preheat the oven to the desired temperature before inserting the vegetables which are to be baked.

New potatoes (little, round, red or small white potatoes) are high in sugar and low in starch and cook very quickly. They steam in about 10 minutes, and bake in 15 or 20 minutes, depending on size. If you eat raw white potatoes, new potatoes are preferable. However, white potatoes shouldn't be eaten raw.

Fresh green lima beans (or other fresh, podded beans or peas): Buy in the pod, shell them, and steam until tender. Fresh green peas are delicious raw.

Yams, Sweet Potatoes, Butternut or Acorn or Hubbard Squash: These may be steamed or baked. Squash may be halved, quartered, or cut up for steaming. For baking, bake sweet potatoes or yams whole. Cut squash in half (or, in the case of very large squash, cut up in serving size pieces); remove seeds if you wish. Bake squash cut side up to conserve juices. Bake squash in covered pan as it may spatter the oven. Whole sweet potatoes or yams in an open pan will not spatter the oven if you don't leave them in too long. Sweet potatoes, yams and winter squash take about thirty minutes to bake, depending on size.

Globe Artichokes: These may be baked in the oven in a covered casserole—no added water is necessary. Just wash and put in casserole wet. Bake at 375 to 400 degrees until just barely tender. Length of time depends on size—45 minutes average. Or steam in as little water as possible; it will take more water than most other vegetables, and will take 15 or 20 minutes, depending on size. The usual way of cooking artichokes, covering with boiling water, is faster, but much more wasteful of nutrients.

To eat artichokes, pull off the leaves, one at a time, and scrape off the tender edible flesh at the base with your teeth. The larger outer leaves are not as tender as the inner leaves. When you reach the "heart," scrape out the fuzz called the "choke" and eat the remaining heart, which is the most delicious part.

Tasty steamed vegetables: Broccoli, cauliflower, green beans, yellow crookneck or zucchini squash, Brussels sprouts, etc.—add parsley, diced celery and celery leaves and/or sweet bell pepper to any vegetable, if desired. Steam in a small amount of water until just barely tender—still crisp, and color unchanged. *Do not overcook*. This is worth repeating and re-emphasizing. If not overcooked, no seasoning should be necessary (even if no parsley, celery or sweet pepper have been added).

Overcooked Brussels sprouts are actually repulsive. Overcooked cauliflower is almost as bad. Don't cook cabbage at all. Cooked cabbage takes a long time to digest, and I can't think of any reason to cook it. Cooking certainly doesn't improve the taste (nor the digestibility or nutritional value). If overcooked,

it is quite unpalatable. If steamed slightly and still crisp and green, it is barely acceptable.

When vegetables of the cabbage family (broccoli, cauliflower, Brussels sprouts, cabbage) are overcooked, they are not only unpleasant to the taste (and smell), they also cause digestive distress.

Corn on the cob: Green corn freshly picked is delicious eaten raw, if not too mature. Several hours after picking, it is no longer a green vegetable. The sugar has turned to starch, which should be dextrinized by heating. If reasonably young and fresh, it is dextrinized and tender in only a few minutes (two to five minutes). If more mature, it may be necessary to steam as long as ten minutes. Usually, steaming longer than ten minutes actually makes mature corn tougher.

Asparagus: Raw asparagus tips are delicious. Snap off the white ends with your hands; they break easily near the edible part. To cook, place in pan at an angle so the tips are not in the water. The tough, discarded ends can be used to prop up the tips. Steam two or three minutes, till barely tender.

Greens: Kale, turnip, dandelion, collard, and broccoli leaves. For greatest nutritional value, eat young tender greens raw. Larger, more mature greens may be steamed in a very small amount of water until just tender. Add diced turnips to turnip greens. Very small turnips are usually mild and sweet enough to be eaten raw. Diced celery and/or sweet pepper may be added when steaming greens. No seasoning is necessary.

Do not use cooked mustard or spinach greens. Mustard greens have a characteristically sharp taste, since they contain mustard oil, an irritant. Spinach, beet greens and Swiss chard are too high in oxalic acid, a calcium antagonist. Small, immature spinach leaves (or mustard or beet greens) may be used raw occasionally in salads. Swiss chard, which is extremely high in oxalic acid, should never be used.

Kale is an excellent green, especially when young and immature, and eaten raw. Broccoli leaves are also greens of high nutritional value. Eat as many as possible raw. Very large broccoli leaves may be steamed.

Jerusalem artichokes, chayotes, kohlrabi: Eat them raw! They have a pleasant taste when steamed slightly, but have a much better taste when uncooked.

Use cooked celery only to season other cooked vegetables—otherwise eat it raw. Strong celery tops may be slightly steamed as an individual vegetable.

Tender celery cabbage should be eaten raw—if tough and stringy, steam it slightly.

Okra: Sometimes palatable raw, if immature. Usually cooked with other foods (soups, casseroles, as a thickener). Tomatoes tend to reduce or neutralize the "sliminess". If you don't like okra, forget it! Foods which have properties that require "neutralizing" are best avoided anyhow.

Use cooked tomatoes seldom, if ever. Cooking tomatoes accentuates their acidic properties.

Salsify (oyster plant): Steam until just tender.

Don't ever cook fresh, raw water chestnuts. I can't think of any possible reason or excuse for cooking this delicious food. It is so excellent and succulent raw, and cooking would really rob it of most of its exceptional qualities. Just compare fresh water chestnuts with canned water chestnuts. The canned variety does, surprisingly, retain its crispness, but the sweet, juicy flavor is gone.

Lettuce is sometimes steamed or "wilted." Very tough blemished outer leaves might be used as a steamed vegetable, but raw dark green lettuce leaves are of great value and should be a staple of the daily diet.

The purpose of "wilting" lettuce with water, heating or vinegar is somewhat nebulous. It completely destroys its delightful crispness, and the use of vinegar adds a toxic ingredient. The enjoyment of wilted lettuce appears to be either a habit, a perverted taste, or a concession to dental or digestive impairment, though it would seem to cause more problems than it ameliorates.

If lettuce must be broken down for temporary adaptation to dental or digestive problems, a less

destructive method would be the use of the blender. Even though oxidation would occur, at least no vinegar or water would be added, and destructive heat would not be applied.

If chicory, endive or escarole are too tough or unpalatable to be used raw, they may be slightly steamed and used as a cooked green vegetable.

Raw, crisp, juicy cucumbers are an excellent addition to salads—even people with impaired digestions can tolerate them if they avoid overmature ones with large seeds and tough skins. Cooking would destroy their palatability and most of their value.

## **2.14 Seasonings**

All seasonings are unhygienic. Raw foods require no seasoning. Lightly steamed or baked individual vegetables should require no seasoning.

When several foods are cut up and combined into a casserole, stew or soup, we are getting farther away from the simplicity of Hygienic food preparation and the pleasant, natural, individual flavors of foods. It is then that we are confronted with "seasoning" problems.

Many people request recipes for such casseroles, stews or soups, for use during the transitional period to Natural Hygiene, to meet the demands of their families, for variety, and for special occasions. Such recipes are therefore included in this lesson, with the admonition that they be used infrequently, and not as a regular part of the diet.

These dishes may be "seasoned" with parsley, celery tops, sweet bell peppers. Tomatoes may be used, sparingly, as seasoning for dishes which do not contain any starches or starchy proteins. Garlic and onions may be used as seasonings, if desired, if care is taken to precook them for twenty minutes; this eliminates the irritation of the mustard oil they contain. Do not use garlic or onions as seasoning if they cause subsequent distress or aftertaste, which they sometimes do. If you do season with garlic or onions, use very sparingly.

Dr. Esser says that occasional, limited use of garlic as a flavoring in the preparation of a cooked food, or rubbing it over a salad bowl, is harmless and inconsequential.

Vogue Vegebase is available in health food stores. It is mostly dried powdered vegetables, and, if you must use a prepared seasoning, Vegebase is preferable to the use of salt, pepper, or other preparations. The sooner you can get away from the use of all such preparations (including Vegebase), the greater will be your progress toward the ideal. All seasonings, even the mildest, are irritants to some extent.

It is also important to remember that most of the senses have a role in digestion. Seeing, smelling, touching and tasting the food all help in sending the proper signals for the secretion of the digestive juices, and their adaptation to the character of the food. Complicated mixtures of foods interfere with this process and make it less efficient as well as digestive problems.

When we compound the problem by adding seasonings (perhaps required for "fancy" recipes or because of jaded appetites), the true taste of individual foods is further disguised. It thus becomes extremely difficult for the digestive system to supply secretions that can adequately cope with these meals, and digestion becomes inhibited and impaired.

If Vegebase (or any seasoning) is used, it should be added just before serving. Cooking with seasoning tends to toughen the food.

### 3. Miscellaneous Recipes

Note: None of these recipes are recommended for regular use. The farther away we get from eating plants as they grow, the greater the destruction of nutritional values. These recipes are provided as less harmful substitutes for conventional recipes.

#### 3.1 Eggplant

Cookbooks often suggest soaking eggplant or dredging it with salt to draw out the "bitter juices". *Do not soak or salt eggplant.* If the eggplant is fresh and not over-mature, it will not be bitter. Select small to medium firm eggplants with shiny skin and deep color. Most eggplant is not tasty when eaten raw. As previously indicated, very young sweet eggplant may be sliced and eaten raw as a sandwich with fillings of sprouts or other raw vegetables. There are many excellent cooked dishes that can be prepared with eggplant, and it is a favorite of many vegetarians who use cooked food.

##### 3.1.1 Eggplant Steaks

Slice in half-inch slices, spread out on cookie sheet. Run distilled water on slices so they are quite wet on both sides. Sprinkle Vegebase sparingly on both sides. Broil lightly on both sides. Turn off broiler and let slices remain in hot oven about ten minutes longer to become slightly more tender. Can be eaten plain as a nonstarchy vegetable, or just dotted with butter before serving.

Or, if desired, put a thick slice of raw tomato (or raw sweet red bell pepper) on each steak and a slice of Swiss unprocessed mild cheddar cheese. Leave in warm oven until cheese is just barely melting, or lightly brown under broiler.

*Variation:* Summer squash (cut in half lengthwise) or turnips (thick slices) may be prepared the same as eggplant steaks.

##### 3.1.2 Easy Eggplant Casserole

2 medium diced eggplants (unpeeled) (dice in rather large pieces)  
2 medium tomatoes, peeled and cut up  
4 strips celery, sliced  
1/2 sweet pepper (red or green) diced  
Vegebase (to taste) (start with one-half tablespoon)

Place all in casserole, add about one inch of water. Steam (covered) on top of stove about three minutes. Add eight ounces of ground cashew nuts (on top). Bake uncovered in 373 degree oven about 20 minutes or until cashews are slightly browned. If eggplant is softer than you like it, try (1) steaming a shorter time than three minutes or (2) browning cashew nut topping under broiler (instead of baking). Serves three or four.

##### 3.1.3 Crumbly Eggplant Casserole

Broil eggplant slices slightly (barely lightly browned). Prepare desired amount of Spanish sauce (see recipe), Grind desired amount of cashew nuts. Put Spanish sauce ground cashews and broiled eggplant slices alternately in casserole (in layers), ending up with Spanish sauce and light sprinkling of ground cashews over the top. Lightly brown under broiler. Should be crumbly, with little or no liquid.

Suggested quantities to serve three or four:

1 large or 2 medium eggplant or 3 or 4 small eggplants (small or medium eggplant are best, large ones may be bitter)

1 recipe Spanish sauce

10 to 12 ounces ground cashews (by weight)

### **3.1.4 Stuffed Eggplant**

Cut raw eggplant in half lengthwise. Scoop out flesh in as large pieces as possible, leaving about one-quarter inch of flesh on the shells. Moisten the pieces and the half shells with distilled water and arrange on a cookie sheet. Sprinkle sparingly with Vegebase. Slightly brown under broiler.

Cut pieces of eggplant into smaller pieces (about one inch). Combine with Spanish sauce (see recipe—one recipe of Spanish sauce for approximately two medium eggplants). Mixture should be moist but not wet.

Put several tablespoons of this mixture into each half-shell. Cover with ground cashews. Alternate two more layers of mixture and ground cashews, with cashews on top. Brown slightly under broiler. End leave in hot oven five minutes longer to tenderize half shells.

*Variation:* Sliced Polly-O All Natural Mozzarella Cheese can be substituted for the ground cashews.

### **3.1.5 Eggplant Surprise**

8 ounces cashew nuts

2 small to medium tomatoes, peeled and cut up

2 strips celery, sliced

1 teaspoon Vegebase

As little water as possible

Blend all together. Start with one-half cup water, add more water if necessary; mixture should be quite thick. Spread thickly on broiled eggplant slices (eggplant steaks—see recipe) and brown very slightly in broiler. This quantity is enough to cover slices from two medium eggplants. This mixture can also be used as a topping for other nonstarchy vegetables.

### **3.7 Spanish Sauce**

4 or five medium tomatoes (peeled and sliced)

1 sweet pepper (preferably red) diced

4 strips diced celery

1 tablespoon chopped parsley

10 medium mushrooms (optional)

Vegebase to taste (optional). If Vegebase is used, use sparingly.

Add small amount of water, about one-fourth cup or less. Tomatoes will supply most of liquid necessary to steam this mixture for just a few minutes, just long enough to slightly tenderize the ingredients. May be used with any nonstarchy vegetable.

To use onions as an ingredient of this Spanish sauce, precook the onions for 20 minutes before adding to other ingredients.

### **3.8 Company Squash**

Use tender young yellow crookneck or zucchini squash or both. Slice slantwise (oval slices) about one-fourth inch thick. Place in casserole with enough distilled water to wet slices thoroughly. Pour off most of excess water. Sprinkle wet slices with Vegebase (sparingly). Sprinkle with paprika (optional). Bake at 375 degrees ten minutes covered, ten minutes uncovered until slightly brown (or brown under broiler). If

firmer squash is desired, cut thicker slices.

### **3.9 Tasty Cauliflower**

Cut into small florets. Steam in minimum amount of water about six to eight minutes until just barely tender. Then toss with small amount of Vegebase and brown slightly under broiler. (If desired, sprinkle with paprika before)

### **3.10 Spaghetti Squash with Sauce**

Sauce:

Diced sweet red pepper  
Parsley, chopped  
Diced celery  
Mushrooms  
Small fresh sliced onion, if desired

If onion is used, precook for 20 minutes. In wok or skillet, stir fry all ingredients in small amount of water—no oil. Cover and allow to steam a few minutes.

Bake spaghetti squash whole at 375 degrees—20 to 30 minutes, depending on size. Cut in half before serving. Run a fork through the hot flesh and it separates into spaghetti-like strands. Put mound of sauce in each cavity. (Seeds may be removed, if desired, before adding sauce.)

### **3.11 Rice**

Long grain rice cooks up light and fluffy—medium rice slightly sticky, and moist short grain rice even stickier.

#### **3.11.1 Plain Cooked Brown Rice**

1 cup Long Grain Rice  
3 cups cold water  
Saucepan with tight lid.

Bring water to boil, add rice and boil for one minute. Turn heat down, cover tightly, and simmer about thirty minutes or until water is absorbed and rice is fluffy and tender. To prevent sticking, don't stir. If fluffy and tender but not dry, put in warm oven uncovered for a few minutes.

#### **3.11.2 Mixed Wild and Brown Rice**

1 cup Long Grain Brown Rice  
2 1/2 cups cold water

Bring water to a boil, pour over rice, cover and bake in 375-degree oven forty minutes or until dry and fluffy. Add more water if necessary (check after 30 minutes to see whether additional water is necessary.) If rice is tender, but too wet, uncover for five minutes or so.

#### **3.11.3 Mixed Rice Casserole**

3/4 cup Long Grain Brown Rice  
1/4 cup Wild Rice  
4 strips sliced celery  
1 large diced sweet red pepper  
1/4 pound sliced mushrooms (optional)

3 cups cold water  
2 teaspoons Vegebase (or Vegebase to taste)

Bring water to a boil, add brown rice, cook five minutes, (simmer). Add wild rice and other ingredients. Bake covered in 375-degree oven about forty minutes, or until rice is tender and fluffy. Check after 30 minutes to see whether additional water is necessary. If rice is tender, but too wet, uncover for five minutes or so.

#### **3.11.4 Stuffed Sweet Red Peppers**

3 large sweet red peppers  
4 strips diced celery  
2 sprigs chopped parsley  
1/4 pound sliced mushrooms  
Vegebase to taste

Steam all but peppers five minutes in small amount of water. Add to plain cooked mixed wild and brown rice (see recipe). Cut peppers in half, remove seeds, and spoon in rice mixture. Bake in covered casserole in 375-degree oven until peppers are tender (about ten or fifteen minutes).

#### **3.11.5 Vegetable Chop Suey with Rice (Starch)**

A few pieces of celery top, chopped  
A few sprigs chopped parsley  
1 large sweet red pepper, sliced (sweet green pepper may be substituted)  
4 strips sliced celery  
2 large strips celery cabbage and/or an equivalent amount broccoli florets and leaves  
3/4 cup freshly shelled green peas  
2 large carrots, cut up in bite-sized pieces  
1/2 cup cauliflower florets  
1/4 cup Jerusalem artichokes, cut up in chunks  
Vegebase to taste (add Vegebase just before serving)

Blend half of the peas in one cup of water. Add the balance of the peas whole, and the other ingredients. Steam ten minutes. Serve over cooked or baked brown rice. Sprinkle alfalfa sprouts, raw snow peas and raw water chestnuts over each serving. If raw snow peas and raw water chestnuts are not available, use frozen snow peas (if desired) and canned water chestnuts, in which case they should both be added to the pot to heat up before serving. Snow peas and water chestnuts, even if not raw, add a crisp tastiness to vegetable chop suey. Serves three or four.

#### **3.12 Vegetable-Sesame Casserole**

Green beans or broccoli  
Cauliflower florets  
Sliced summer squash, zucchini, yellow crookneck or Pattypan (or thinly sliced turnips)  
Sesame Seeds and Vegebase, half and half, mixed

Steam green beans (or broccoli) and cauliflower in small amount of water for five minutes. Sprinkle with small amount of Vegebase and sesame seed mixture. Top with slices of squash or raw turnips. Sprinkle with balance of Vegebase-sesame seed mixture. Brown lightly under broiler. (Squash or thin turnip slices will tenderize under broiler.)

#### **3.13 Zucchini Cheese Casserole**

4 medium zucchini

2 medium tomatoes, peeled and cut up  
4 strips celery, sliced  
1 small sweet pepper, diced  
Vegebase to taste

Place all in electric skillet (or casserole on top of stove). Steam until tender, about six to eight minutes. Turn off heat. Lay slices of unprocessed cheese over top. Cover and serve when cheese is just barely melted.

### **3.14 Lentil Casserole**

1 cup lentils  
4 strips diced celery  
1 small diced sweet pepper  
2 cups water  
Vegebase to taste

Steam lentils approximately 15 minutes or until almost tender. Add celery and pepper and steam five minutes longer. Do not overcook. Add Vegebase before serving.

### **3.15 Protein Vegetable Chop Suey**

A few pieces of celery top, chopped A few sprigs of chopped parsley  
1 large sweet pepper, sliced (red preferred) 4 strips sliced celery  
2 large strips celery cabbage and/or an equivalent amount of broccoli florets and leaves  
3/4 cup freshly shelled Green Peas  
1 cup of sliced Bok Choy or other Chinese vegetables  
1 cup mung bean or soybean sprouts  
Vegebase to taste (add Vegebase just before serving)

Blend half of the peas in one cup of water. Add the balance of the peas whole, add half of the bean sprouts and all of the other ingredients, except the Vegebase, which is to be added just before serving. Steam for ten minutes. Serve over the remaining raw bean sprouts, or sprinkle the raw bean sprouts on top. Cooked unsprouted soybeans may be substituted for the bean sprouts, and served with alfalfa sprouts. See suggestions for snow peas and water chestnuts in Starch Vegetable Chop Suey recipe, which may also be used with this Protein Vegetable Chop Suey. Serves three or four.

### **3.16 Lentil Soup**

1 cup lentils  
A few pieces celery tops, coarsely chopped  
4 strips sliced celery  
A few sprigs parsley, chopped  
1/2 cup coarsely chopped kale or Bok Choy  
3 cups water  
Vegebase to taste

Simmer lentils 20 minutes, add vegetables, simmer five minutes longer. Soup should be thick, not watery. If too thick, add a little more water. Add Vegebase before serving.

### **3.17 Millet-Squash Casserole**

1/2 cup Millet, browned slightly (dry) in skillet  
2 cups boiling water

Cook about 20 minutes, then add four strips sliced celery, one small sweet bell pepper, diced, and cook about five minutes more. Add three sliced zucchini squash and cook a few minutes longer until tender and all water is absorbed. Add Vegebase to taste before serving.

### **3.18 Vegetable Soup or Stew**

Soup should be very thick, even less water for stew. Start with a small amount of soaked garbanzos, beans, or split peas. (See bean instructions.) Cook beans or peas until soft, add vegetables ten minutes before serving, except add summer squash two minutes before serving. If onion is desired for seasoning, add at least twenty minutes before serving, while beans are softening.

Any combination of vegetables may be used, with the exception of tomatoes.

### **3.19 Vegetable Soup or Stew with Rice or Wild Rice (or Barley)**

(An economical way to use wild rice)

Omit beans or peas. Cook rice separately until tender. Cook vegetables five to ten minutes, as in previous recipe, and add rice and Vegebase. (Barley may be used instead of rice, using the same method.)

### **3.20 Vegetable Soup with Potatoes**

Omit beans or peas. Cook cut-up potatoes (unpeeled) until almost tender, add vegetables and cook five to ten minutes longer, add Vegebase.

### **3.21 Vegetable Soup with Fresh Podded Beans or Peas**

Cook fresh beans or peas until almost tender. Add vegetables, cook five to ten minutes longer. Add Vegebase to taste.

Tips for Vegetable Soups or Stews: Start with small amount of water, you can always add more. If using dried beans or peas, don't use starchy vegetables like potatoes or carrots. Fresh podded beans or peas may be used with carrots, if desired. Never use cabbage in soup or stew. If cabbage family vegetables (cauliflower, broccoli, Brussels sprouts) are used, great care must be taken not to overcook them. Celery, green beans, kale, Bok Choy, carrots and parsley are especially good in soup. Parsley may be cooked in the soup, or add a small amount of raw chopped parsley before serving.

### **3.22 Broccoli-Cashew Soup**

1 1/2 cups broccoli florets  
1/2 cup tender broccoli stems (do not use tough fibrous parts)  
1 small onion, sliced  
1 clove fresh garlic, chopped  
3 strips sliced celery (with celery tops)  
3 sprigs parsley (chopped)  
1 small sweet red pepper, cut up  
1/2 cup cashews (ground fine in mill or blender)  
4 cups water  
Vegebase to taste

Precook onion and garlic ten minutes, add broccoli stems and cook five minutes more; add celery, parsley and red pepper and cook two or three minutes longer. Add the raw broccoli florets, the cooked vegetables and liquid to the ground cashews and blend. Place mixture in soup pot with enough

additional water to total approximately four cups liquid. Simmer a few minutes until it thickens. If too thick, add more water; if too thin, add more ground cashews. Add Vegebase to taste.

### **3.23 Summer Squash-Sesame Seed Soup**

Same ingredients and instructions as fox Broccoli-Cashew Soup. Use approximately one-fourth to one-half cup of sesame seeds to eight medium zucchini or yellow squash. Or try using half sesame seeds and half cashews for a different flavor.

### **3.24 Potato Broccoli Soup**

Blend two medium potatoes (unpeeled) with one small onion in three cups water. Heat until it thickens—it must be watched, it can easily burn. Cook over slow burner for about ten minutes, stirring to prevent burning. Add optional amounts of cut-up broccoli, diced celery, celery tops, parsley and sweet red pepper, and continue cooking for ten minutes longer. If too thick, add more water. Add Vegebase to taste before serving.

### **3.25 Vichysoisse**

Cut up two leeks or four large spring onions (white part only) and put in blender with two medium cut-up potatoes (unpeeled), one large cut-up carrot, and two cut-up strips celery. Add one cup water and blend. Put in saucepan, add one to 1 1/2 cups more water. Heat to boiling point and turn down to barely simmering for ten to fifteen minutes or so (until thick). Add 1/2 cup heavy cream (preferably unpasteurized). May be served hot or cold. Add Vegebase just before removing from the heat. Serves two or three.

### **3.26 Split Pea Soup**

1 cup dried green or yellow split peas  
3 to 4 cups water  
1 small chopped onion  
1 or 2 cloves minced garlic

Combine and simmer for approximately one hour. If desired, mash before adding other ingredients. Add two strips sliced celery, two sprigs chopped parsley, one small chopped sweet pepper, and simmer five minutes longer. If desired, add sliced zucchini or yellow squash and simmer two minutes longer. Soup should be very thick. Add Vegebase before serving. Serve with sprinkling of alfalfa sprouts.

### **3.27 Beet Borsht**

Cook sliced beets slightly (about five to ten minutes). Put in blender with small amount of raw beets. Suggested amounts: two large beets cooked, two small beets raw. Add to blender mixture two strips sliced raw celery, two small raw carrots. Use water from cooked beets and add more water as necessary to blend. Should not be too thin. Add Vegebase. Chill. Add sour cream or yogurt to taste before serving.

### **3.28 Buckwheat**

Buckwheat isn't a wheat—it isn't even a grain, but it is used as grains are used. It is a cultivated annual herb, native to Siberia, grown chiefly in the Eastern United States, Northwest Europe and in the mountainous districts of Japan. The groats are actually the fruit rather than the seed (as most grains are) of the buckwheat plant.

It is sold as raw (light) buckwheat groats, roasted (dark) buckwheat groats, ground buckwheat groats,

and buckwheat flour. The dark groats have a distinctive taste which most people either love or dislike intensely. The light milder groats taste a little like barley.

Buckwheat flour sold in supermarkets, and buckwheat pancakes in restaurants, may not even contain any buckwheat, but may be a combination of corn, rye, wheat and other ground cereals. Buckwheat groats are available in health food stores and natural food stores.

Buckwheat is usually associated with pancakes, but Hygienists usually use the groats in casseroles.

### **3.28.1 Kasha (Buckwheat Groats)**

3/4 cup buckwheat groats  
4 strips sliced celery  
1 small diced sweet pepper

If light buckwheat groats are used, brown them slightly (dry) before cooking. Pour approximately 3Vi to 4 cups boiling water over combined ingredients. Simmer until tender—do not overcook. Be watchful so it won't burn—may need more water. Serves three or four. Add Vegebase to taste before serving.

### **3.28.2 Buckwheat Pancakes**

Since most people who enjoy buckwheat associate it with pancakes, I have endeavored to offer the least harmful recipe possible for buckwheat pancakes. This recipe is a long way from Natural Hygiene, and should seldom, if ever, be used.

1 tablespoon dry yeast  
1 tablespoon honey or other sweetener  
2 cups Buckwheat flour  
(ground in blender or mill from light raw buckwheat groats)

1 to 2 cups water or raw potato water or unpasteurized buttermilk (raw potato water: one small diced potato (unpeeled), put in one cup measure, fill with warm distilled water, and blend. Good substitute for milk.) Batter should be thin

Dissolve yeast in lukewarm water with honey. Let stand ten or fifteen minutes or longer (until bubbly). Add balance of liquid. Add flour. Mix well. If baked on natural soapstone griddle, no oil or butter will be necessary. If baked on regular uncoated griddle, add approximately one tablespoon melted butter or oil to batter, and it may be necessary to also lightly oil the griddle. The griddle should be hot enough for water to jump around. If water disappears, it is too hot.

### **3.28.3 Buckwheat Pancakes (Overnight Recipe)**

Soften yeast in 1/4 cup water with half of honey. Let set until bubbly. Add balance of liquid and flour. Beat. Batter should be thin. Pour batter into large pitcher, cover, and set in warm place overnight. In morning, add other half of honey. Stir thoroughly. Bake.

## **3.29 Vegeburgers**

These may be made with almost any combinations of vegetables and nuts (and/or seeds). If any starchy vegetables are used (such as carrots), combine with ground raw peanuts. If no starchy vegetables are used, combine with ground sesame seeds, sunflower seeds, almonds, pecans (or other nuts).

Suggested ingredients: Celery, Sweet Pepper, Parsley, Cauliflower, Carrots, Green Beans, Broccoli, Bok Choy, Turnips, Kohlrabi.

Coarsely shred vegetables by hand or in food processor. It will be necessary to blend approximately half of the vegetables in a small amount of water and combine them with the shredded vegetables. Add

ground nuts and/or seeds. If too dry add more water; if too wet, add more nuts. Shape into patties and broil on both sides until slightly browned. These make great "sandwiches" between leaves of romaine lettuce and are good hot or cold. They do not hold together as well as burgers that use a raw egg in the mixture, but, if handled carefully, are quite acceptable, and taste great.

### **3.30 Beans**

Soybeans contain about three times as much protein as other beans, and little or no starch. Dried soybeans take a long time to cook—they may take 3 1/2 to 5 hours. Dried soybeans should be soaked overnight in distilled water to cover, in refrigerator. Next day, add more water to cover (use the soaking water) and cook until desired softness is attained, adding more water as necessary. If the soybeans are to be used in a baked casserole, or ground, or chopped, they should not be cooked until soft, but removed when still rather firm and chewy. Cooking time may be shortened (perhaps halved) by freezing after soaking (in soaking water) several hours or over night.

Some nutritionists advocate longer soaking of soybeans (24 to 48 hours) and the discarding several times of the soaking waters, in order to be certain of the destruction of the toxic anti-enzyme factor that is said to block the digestion of proteins. The longer soaking time shortens the cooking time. (All dried beans should be soaked, preferably overnight, before using.)

Green soybeans will take much less time to soften, probably from 15 to 30 minutes, depending on variety and condition, and need not be soaked. Other beans fresh from the pod (limas, cranberry beans, black-eyed peas, etc.) will soften more quickly, and only need a brief cooking period—no soaking.

Sprouted soybeans (or other sprouted beans) may be eaten raw, or steamed a short time to improve their palatability.

Please refer to Lesson 26 for a discussion on using the soaking water versus discarding it. You will find it in the section on sprouting.

#### **3.30.1 Soybean Casserole (or any dried beans)**

Soak one cup dried soybeans overnight in two cups distilled water (in refrigerator). Cook until just firm and chewy. Add two strips diced celery, a few chopped celery leaves, a few sprigs of parsley (chopped), one small diced sweet pepper. Add enough water to cover. Cover casserole and bake in 375-degree oven until done, with lid removed during last half hour of baking. Soybeans may take an hour of baking.

This recipe may also be used for any dried beans. Add Vegebase before serving. Dot with butter if you use it.

#### **3.30.2 Crunchy Soy Bean Treat**

Soak and cook dried soybeans as usual (see Soybean Instructions)—not too soft, should still be rather firm and chewy.

Grind or chop to consistency of coarsely chopped nuts. Add diced celery (about two strips per three servings); a few chopped celery leaves; a few sprigs chopped parsley; one diced sweet pepper. Place in casserole or loaf pan. Add the soybean liquid and/or water to almost cover. Bake uncovered in 375-degree oven until lightly browned and liquid is absorbed. Add butter when serving, if you use it—also Vegebase to taste.

#### **3.30.3 Soybean Loaf (or Garbanzo Bean Loaf)**

Soak and cook dried soybeans or garbanzo beans as usual—not too soft, should still be somewhat firm and chewy. Grind or chop to consistency of chopped nuts (not too coarse). Add diced celery (about three

strips per three servings); a few chopped celery leaves; a few sprigs chopped parsley; one diced sweet red pepper; about one-half cup broccoli florets, cut up in small pieces; and about one-half cup zucchini squash, cut in thin half slices per three servings). Mix ingredients together lightly, add Vegebase to taste, and add enough cooking liquid from the beans (and/or water) so it will hold together. Put in loaf pan, top with slices or strips of sweet red pepper or pimiento. Bake uncovered in 375-degree oven until lightly browned, but still somewhat moist (about twenty minutes).

### **3.30.4 Bean Soup (Dried Pea Beans, Navy Beans, Cranberry Beans, etc.)**

Soak one cup dried beans overnight in two cups distilled water (in refrigerator). Add two cups water. Cook until almost soft. Add more water as needed. Add one clove chopped garlic and one small sliced onion and cook ten minutes longer. Add four strips sliced celery, a few chopped celery leaves, a few sprigs chopped parsley, one small diced sweet pepper, and an optional amount and variety of sliced vegetables (bite-sized pieces). Cook ten minutes longer. If too thick, add more water. Add Vegebase to taste before serving.

### **3.30.5 Bean Pot**

Use any beans fresh from the pod: Limas, Soy, Black-eyed Peas, Cranberry Beans, or any other freshly shelled beans.

Cut up and place in bottom of pot: four strips celery, two medium yellow summer squash or zucchini squash. Sprinkle with one teaspoon Vegebase. On top of cut-up vegetables, put one cup of beans which have been precooked for ten to fifteen minutes until almost soft. Over top, sprinkle one teaspoon Vegebase. Add water carefully around side about halfway up. Cover and bake in 375-degree oven for one-half hour. Uncover and bake a little longer (if you like it drier). If you like it quite dry, use less water. Serves two or three.

### **3.31 Rice Crackers**

Rice Crackers made of brown rice and water only (no salt or leavening) can be purchased in health food stores, or you can make them yourself.

Grind brown rice in blender or grinder, add a little Vegebase (if desired), and add enough water to hold it together into a dough. Roll very thin between two sheets of wax paper. Place on cookie sheet, and mark off into cracker size with knife. Bake at 325-degrees for about ten minutes or until pale or golden brown.

### **3.32 Clabber or Cottage Cheese**

Put whole raw milk in individual cups or glasses (covered with thin cloth or paper towels) in a warm place (about 75 to 85 degrees) about 30 to 48 hours (may take less time or longer, depending on milk and temperature) until thick and custardy. (Don't move it, mix or stir.) Sour cream will be on top. This will keep in the refrigerator about five days. The secret of successful clabber is an even warm temperature. Clabber may be eaten with the fruit meal.

If you are not successful in producing clabber without a "starter", use two tablespoons of natural sour cream per quart of raw milk, mix well, and proceed as above. Usually this clabber sets in twenty-four hours. (Or use two or three tablespoons of Borden's Buttermilk, or try adding lemon juice to the sweet milk to start the souring or clabbering process.)

For cottage cheese, put clabber in cheese cloth or nylon net bag and let drip six to eight hours.

### **3.33 Desserts (If You Must!)**

#### **3.33.1 Uncooked Fudge Brownies**

1/2 cup rolled oats  
1/2 cup carrots  
1/2 cup grated coconut  
1/2 cup carob powder  
1/2 cup raisins (soaked 15 minutes)  
8 medium dates (more or less, depending on how sweet you want it)  
water (as necessary)

Blend or grind oats into flour, add carob powder and coconut, add soaked raisins to dry ingredients. Blend carrots and pitted dates in minimum amount of water. Add to the dry ingredients, mixing well. Add as much water as necessary to make a thick drop cookie consistency. Drop by teaspoonfuls on pliofilm and roll up in groups of four or six, or drop into miniature paper muffin cups or paper petit four cups. Refrigerate, if to be used same day. Otherwise, store in freezer. These do not need thawing.

If you like them sweeter, use more dates. If less sweet, use fewer dates. Actually, proportions of all ingredients are optional. No cooking or baking is necessary, because all ingredients (including the rolled oats) are excellent uncooked.

#### **3.33.2 Date Coconut Pie**

Moisten fresh grated coconut and pat into pie plate for crust. Chill for an hour or so.

Blend bananas and pitted dates in as little water as possible (mixture should be quite thick) and pour over the crust. Put coconut liquid in blender and add small pieces of peeled coconut until the mixture is thoroughly blended and thick. Spread over the pie. Top it with shredded coconut and pitted dates, whole or sliced. Chill for at least two hours.

#### **3.33.3 Fruity Banana Coconut Cream Pie**

Mix equal parts of fresh grated coconut and chopped dates and pat into pie plate for the crust. Moisten with water, if necessary. Chill for an hour or so. Fill with sliced bananas. Blend any subacid fruit with unpasteurized cream and pour over the sliced bananas. (Mixture should be thick.) Top with whipped cream and sprinkle with grated coconut. Chill for at least two hours before serving.

#### **3.33.4 Creamy Ice Fruit**

1/2 cup sweet cherry juice or sweet grape juice or sweet apple juice  
3/4 to 1 cup water (or a little more, if needed)  
1 large or two small bananas  
1 large or two small avocados  
4 tablespoons carob powder  
15 to 20 pitted dates (depending on size)

Blend dates in juice and water. Add pieces of avocado a little at a time, while blending, then add slices of banana and carob. If more liquid is needed to blend, add as little water as possible. Should be very thick and creamy. Will freeze in refrigerator-freezer without ice crystals if thick enough, and if served shortly after freezing. If not served the same day, thaw slightly before serving.

### **3.33.5 Coconut-Carob Pudding**

Blend eight ounces warm distilled water (or coconut liquid, or mixed) with eight ounces raw, peeled, cut-up coconut meat. Add eight cut-up dates. Blend. Add enough carob powder to make quite thick (approximately eight tablespoons—more or less). May be chilled or frozen. If frozen, remove from freezer one hour before serving.

### **3.33.6 Coconut-Carob Ice Cream**

Blend one cup of warm distilled water with one cup of fresh coconut and cool in refrigerator. Use more water, if necessary. When cool, blend again. Add ten or more cut-up soft dates and enough carob powder to make quite thick. May be frozen or eaten as is. If frozen, remove from freezer one hour before serving.

### **3.33.7 Carob Ice Cream Pudding**

Blend eight ounces unpasteurized cream or unpasteurized half cream and half milk with eight cut-up dates. Add one or more bananas, if desired. Add enough carob powder to make it quite thick. May be chilled or frozen.

### **3.33.8 Fruit Ice Cream**

Blend twelve cut-up dates with flesh from one large or two medium mangos, or four or five medium sweet peaches, or two or three medium bananas. If necessary, add one or two tablespoons unpasteurized cream to start blending. Whip eight ounces unpasteurized cream, fold into the fruit mixture. Freeze in ice cube trays, stirring twice during the freezing process to prevent the formation of ice crystals.

### **3.33.9 Carob Ice Cream**

Blend eight ounces raw cream or raw half and half with seven or eight cut-up dates. Add one or two bananas, if desired. Add enough carob powder to make it quite thick. May be frozen or eaten as is.

## **3.34 Party Punch**

Not recommended, but preferable to punch recipes using artificial flavorings and/or alcoholic ingredients. This is the only recipe in the dessert section of this lesson that is (basically) not uncooked, the juices having been pasteurized, although a few of the previous recipes contain a small amount of such unpasteurized juices, along with the other ingredients, which are uncooked.

Mix three parts of unsweetened pineapple juice with one part of cherry juice (from health food store). Add small amounts of crushed pineapple (unsweetened) and whole fresh strawberries or soaked dried cherries. The taste is delicious and will satisfy (more or less) those who just must have a party drink.

[Home](#) > [Lesson 27 - Preparing And Serving Foods For Best Nourishment, Part II](#) > 4. Recipe Conversions

## **4. Recipe Conversions**

"Before"	"After"
----------	---------

1 ounce chocolate	3 tablespoons carob powder + 1 tablespoon oil
1 cup sugar	3/4 cup honey (reduce liquid in recipe by 1/4 cup and lower oven temperature by 25 degrees)
1 cup sugar	1 cup molasses (reduce liquid by 1/3 cup)
1 cup sugar	3/4 cup date sugar
1 tablespoon flour (used as thickener)	1 tablespoon potato starch
1 package active dry yeast or 1 cake compressed yeast	1 tablespoon active dry yeast
1 cup heavy sour cream	1/3 cup butter and 2/3 cup sour milk
1 cup thin sour cream	3 tablespoons butter and 3/4 cup sour milk
1 cup sour cream	1 cup plain natural yogurt
1 cup butter	2/3 cup oil
1 small fresh onion	1 tablespoon dried minced onion, rehydrated
1 small garlic clove	1/4 teaspoon garlic powder or 1/2 teaspoon dried garlic, rehydrated

These equivalents may be used as substitutes in recipes. Some of them are only a little better than the original ingredients. Some are no better—for convenience only. If you must make ice cream or baked "treats," the best sweetener would be seeded, cut-up dates, blended with some of the liquid of the recipe, in optional amounts, the less the better.

[Home](#) > [Lesson 27 - Preparing And Serving Foods For Best Nourishment, Part II](#) > 5. Questions & Answers

## 5. Questions & Answers

**When we eat cooked food in restaurants, we don't know how it has been cooked. It may have been cooked in a pressure cooker, a microwave oven, a charcoal broiler, or aluminum cooking utensils may have been used. How can these hazards be determined and avoided?**

If you eat cooked food in a restaurant, it is not only subject to the hazards you mention, but it will also contain salt, probably sugar (even in vegetables), and probably pepper and other irritants. It may also contain monosodium glutamate; corn starch or flour for thickening; or other unknown additives. The only way to avoid all of these things is to avoid eating cooked food in restaurants. If you do decide to partake, do the best you can, depending on circumstances. A baked potato is fairly safe, except for the sprout retardant on the skin, and the aluminum foil in which most of them are baked. Order it to be served uncut—otherwise you may find a piece of aluminum foil in your mouth. Sometimes you can get a plain cooked vegetable without seasoning.

Some restaurants cook certain dishes to order, and you can request "no seasoning." In most Chinese restaurants you can get vegetable chop suey with raw bean sprouts and snow peas and without monosodium glutamate, or corn starch or seasoning. Some "natural food" restaurants do a fairly good job. Some salad bars are fairly good.

But any time you eat, in a restaurant, be prepared to compromise. Sometimes, rarely, you can find a friendly and cooperative restaurant owner or manager who will do things your way. Good luck!

### **Most conventional nutrition charts advise against using nuts, because they are so high in fat. Why do Natural Hygienists use so many nuts?**

Conventional diets contain so much fat already (mostly animal fat) that any additional fat is contraindicated. Of course, conventional diets include flesh foods as the major protein source, while Hygienic food programs look to nuts and seeds for concentrated protein. The major sources of fat in the Hygienic diet are nuts, seeds and avocados, which contain unsaturated fat (which conventional nutritionists admit is superior to animal fat). It is true that even Hygienists should not gorge on nuts and avocados, but should eat them sparingly.

Since nuts and seeds are also the major sources of concentrated protein in the Hygienic diet, they are important elements of the food program. Some Hygienists use two to four ounces of nuts and/or seeds almost every day, which would be considered maximum amounts. Many Hygienics use them less frequently, perhaps three or four times weekly (sometimes even less) and get along very well.

### **Is it advisable to eat a protein meal and a starch meal every day?**

No. That would comprise a large amount of concentrated food on a daily basis. Most people would, sooner or later, find that this practice would overburden their digestions. A protein meal three or four times weekly and a starch meal two or three times weekly would be adequate for most people (many would want less), planning protein and starch meals for different days, and filling in with fruit and salad meals. Some people might want up to four or five protein meals weekly and four or five starch meals weekly. This would be quite a lot of concentrated food, and would involve using both a protein meal and a starch meal on some of the days. Actually, starchy meals should not necessarily be included on a regular basis. They are filling, satisfying meals at the time they are eaten, but such foods as grains and legumes (even, to some extent, when sprouted) burden the organism with their digestion.

Potatoes are much easier to digest, and are a good choice for a cooked starch meal, but should not be used everyday, nor in large quantities. Sweet corn (unless freshly picked) is starchy; fresh peas are starchy; both can be eaten without cooking.

The coconut, starchy protein, eaten raw, is a good food to use for some of your starch meals.

Chestnuts, another starchy protein, can be used for starch meals when in season. But you certainly don't need a protein meal and a starch meal on a daily basis.

### **Why should the oven be preheated to the desired temperature before inserting your vegetables which are to be baked?**

The cooking time will be shortened.

[Home](#) > [Lesson 27 - Preparing And Serving Foods For Best Nourishment, Part II](#) > Article #1: Your Probing Mind by Virginia Vetrano, B.S., D.C.

### **Article #1: Your Probing Mind By Virginia Vetrano, B.S., D.C.**

#### **How, and in what, should you steam vegetables?**

If you must compromise and eat some cooked food, then you should steam most vegetables whole and uncut, not grated or sliced, etc. Most vegetables need no preparation for steaming except to be well cleaned. Very large carrots may be sliced in two; rutabaga may be cut into medium-sized pieces; and large beets or turnips may be cut in quarters. Save the outer leaves of the lettuce that are not sufficiently pretty or that are cracked a bit too much to be savory in a salad; wash them well and place approximately three layers of them in the bottom of your cookware. Place the whole, uncut, cleaned vegetables on top of the lettuce leaves. Cover and start the flame moderately high. After two minutes turn the flame down to medium. Add no water to the pan. The water clinging to the lettuce and inside the cells of the lettuce forms the moisture for steaming the vegetables. No extra water is needed except perhaps when steaming large potatoes or carrots, etc. Then you may choose to use a steam rack.

We do not use the steam marvel or a steam rack for all vegetables for several reasons. First, it tempts you to add more water to the casserole. The water becomes steam, condenses on the lid and flows down over the vegetables anyway. Because of a use of more water than necessary for steaming, the vegetable is tasteless when the vegetable is done, and you throw it away, thereby losing valuable nutrients.

Whereas, if the vegetable is steamed in only the water clinging to lettuce leaves and the vegetable itself, it will be concentrated at the end of the steaming process. This cooking juice will taste good because it is concentrated and contains many minerals and vitamins and may be eaten with the vegetable. Lettuce prevents scorching, if you fail to watch the cooking time carefully. The lettuce is used only as a base upon which to cook other foods, and it should not be eaten with the food which you steam.

Spinach, beet tops, and other leafy vegetables have a surplus amount of water on their leaves after washing, which must be poured off prior to cooking. As the cellulose breaks down in these foods from the heat, much fluid leaks out into the cooking vessel and prevents burning and serves as water for steaming the vegetable itself. Consequently, no lettuce leaves are necessary for this type of vegetable. All types of small summer squash require lettuce leaves at the bottom in order to steam them whole without scorching. Steaming vegetables whole without cutting them at all saves minerals and vitamins.

The less you cook the vegetables, the better for you, so steam them just enough to warm them, without changing their natural shape or color.

We do not advocate the use of aluminum, stainless steel, or teflon. Aluminum combines with the acids in the foods forming poisonous aluminum compounds. Stainless steel cookware contains nickel and chromium that bleed into the foods when used. Teflon is highly poisonous as it contains fluorine and gives off poisonous gases under certain conditions. If chipped, and pieces enter the food, it could be very toxic. The only utensils left to cook in which have no known strike against them are opaque glass ware and fine baked enamel ware. If the enamel is chipped, it is best to purchase new cookware.

### **Please explain why fried foods are not good for you.**

Cooking food by any method destroys much of its vitamin and mineral content. Some minerals are lost in the vapor; some are converted into inorganic minerals, which are no longer usable and therefore toxic, and others are lost into the cooking water. Vitamins are destroyed in much the same fashion.

Frying is even worse on food because oil, requires a higher temperature to boil than water. The higher the temperature, the greater the destruction of food. When frying food, it is usually cooked to a "golden brown" or a little darker. This beautiful golden brown that people love so much is a cancer producing substance. The brown on any food that has been browned by cooking is carcinogenic.

In addition the oil itself becomes a carcinogen. It has long been known that heated hydrocarbons can cause cancer. The longer they are heated and reheated and heated again, and the higher the temperature the more carcinogenic they become. Oils are hydrocarbons. The next time you desire french fries just remember that fast food chains change their oil only once a week or less. Also remember that there is more cancer of the stomach and colon than any other area of the gastrointestinal tract. Foods, the decomposition products of foods, and poisonous chemicals from cooking foods are retained in the stomach and colon for a longer period of time than in any other part of the gastrointestinal tract. Their irritating effects probably play a major role in the development of cancer of these organs.

### **Are spices harmful to one's health?**

Yes, they are. It is much better to refrain from using spices. Some spices are extremely poisonous while others are only moderately so. A substance is a food if it is capable of being used by a particular living organism in any of its metabolic processes. If a spice contains poisons and other substances that cannot be used by the organism in making living cells or in any of its functions then it becomes a poison in relation to the living organism, even if it contains minerals, vitamins, proteins and other nutrients. Spices contain substances which cannot be used by the body and if a substance can't be used, it wastes precious nerve energy in expelling it to prevent damage to the body's vital organs. Spices are harmful in proportion to their toxin concentration. They waste nerve energy and cause enervation in proportion to the amount of energy expended in excreting the noxious substances.

Because of the toxic substances contained in spices, they cause irritation to the lining of the stomach and intestines. In fact some of them, such as mustard, cause bleeding of the stomach worse than aspirin, when taken in large quantities such as the amount some people put on their hot dogs.

Spices do not enhance digestion as we have been taught. On the contrary, because of the

irritation they produce digestion is impaired. Besides the irritation to the gastrointestinal tract which may lead to inflammation and ulceration, spices irritate all the tissues inside the body with which they come in contact.

The latest theory in the production of arteriosclerosis is in line with Hygienic theory-that arteriosclerosis begins with an initial irritation, followed by inflammation of the arterial lining with the deposition of fatty material and finally calcium. Spices are definitely irritants and to continue using spices when you know how they are irritants to every tissue with which they come in contact is tantamount to saying "I don't care if I get arteriosclerosis, or gastritis, ulcers or cancer."

Lesson 29 will discuss the harmful effects of condiments in more detail.

[Home](#) > [Lesson 27 - Preparing And Serving Foods For Best Nourishment, Part II](#) > Article #2: Hygienic Considerations In The Selection of Foods By Ralph C. Cinque, D. C.

## **Article #2: Hygienic Considerations In The Selection of Foods By Ralph C. Cinque, D. C.**

The selection of foods for optimum health requires that many factors be considered, including nutrient content, ease of mastication, deglutition, digestion, absorption and assimilation, presence or absence of irritant, the amount of vegetable fiber (which could be too little in the case of refined foods, or too much in the case of mature kale), gustatory satisfaction to the unperverted taste, and the effect on blood alkalinity. An ideal food would contain a broad array of nutrients, would be delicious, would contain a moderate amount of fiber, would be easy to eat and digest in the raw state, would possess no irritants or digestive antagonists and would leave an alkaline ash after metabolism. Applying these criteria, we find that there are virtually no perfect foods. Most fruits and vegetables, for example, contain at least minute amounts of oxalic acid, which is a mild irritant and which has a binding effect on calcium. Tannic acid is contained in the skins of some nuts (particularly almonds) and this, too, is a mild irritant. Lettuce is said to contain lactucarium, a mildly toxic alkaloid with soporific effects. This is particularly true of head lettuce. Beans contain trypsin-inhibitors, aflatoxins and purine bodies which raise serum uric acid levels. Grains contain much phytic acid which binds minerals like zinc and iron, impairing their utilization by the body. It should be obvious that perfect foods (like perfect health) are a theoretical ideal, not a reality.

From a *Hygienic* standpoint, there are three major tenets that guide us in the selection of foods. These tenets enable us to construct a diet that is philosophically and physiologically ideal for the human species. We will admit beforehand that due to various anatomical and physiological weaknesses and defects, not everyone can adhere to the philosophical dietary ideal with complete success. However, before alterations and deletions are made, it is important that we determine what constitutes an ideal diet, a truly natural diet, and then be guided accordingly. Our three major tenets are that:

1. Whole foods are superior to fragmented and refined foods.
2. Raw foods are superior to cooked foods.
3. Plant foods are superior to animal foods.

These three principles summarize *Hygienic* philosophy regarding food selection, and we will expound upon each in turn.

## 1. The Superiority Of Whole Foods

The fact that whole natural foods are superior to refined foods such as white sugar, white flour, polished rice, requires no substantiation to the readers of this magazine. However, we must emphasize that *any* fragmenting of whole food destroys nutrients and lessens the suitability of that food as an article of diet. Whole carrots contain more complete nourishment than carrot juice. Brown rice is better food than rice polishings. Whole wheat is superior to wheat germ. Consider the following experiment conducted by Weston A. Price, D.D.S., the renowned author of *Nutrition and Physical Degeneration*.

"Three cages of rats were placed on wheat diets. The first cage received whole wheat, freshly ground, the second received a white flour product, and the third was given a mixture of bran and wheat germ. The amounts of each ash, of calcium as the oxide, and of phosphorus as the pentoxide and the amounts of iron and copper present in the diet were tabulated. Clinically, it was found that there was a marked difference in the physical developments of these rats. The rats in the first group, receiving the entire grain product, developed fully and reproduced normally at 3 months of age. These rats had very mild dispositions and could be picked up by the ear or tail without danger of their biting. The rats fed upon white flour were markedly undersized. Their hair came out in large patches and they had very ugly dispositions, so ugly that they threatened to spring through the cagewall at us when we came to look at them. These rats had tooth decay and they were unable to reproduce. The rats fed upon bran and wheat germ did not show tooth decay, but they were considerably undersized and they lacked energy. The wheat germ was purchased from the miller and hence was not freshly ground. The wheat given to the first group was obtained whole and ground while fresh in a hand mill. It is of interest that notwithstanding the great increase in calcium, phosphorus, iron and copper present in the foods of the last group, the rats did not mature normally, as did those in the first group. This may have been due in large part to the fact that the material was not freshly ground, and as a result they could not obtain a normal vitamin content from the embryo of the grain due to its oxidation. This is further indicated by the fact the the rats in this group did not reproduce, probably due in considerable part to a lack of Vitamins B and E which were lost by oxidation of the embryo or germ fat."

This account demonstrates how important it is to distinguish between the nutrient content of a food and its overall biological effect. It has been shown repeatedly that eating wheat bran impedes iron absorption, despite the fact that it contains abundant iron. This may be the result of mechanical factors, or, perhaps it is the result of the high phytate content of the bran. In any case, it proves that foods cannot be evaluated solely on the basis of mathematical tables of nutrient analysis.

At first glance fragmented foods may seem to be more nourishing than whole foods. Dried apricots, for example, score much higher in calcium and iron than do fresh apricots. Quite obviously, if we extract the water from the apricots, we can triple or quadruple the number of fruits we are comparing, and thereby shore up higher nutrient values. This seeming enhancement is, of course, a figment of the mind. Whole foods offer the most complete nutrition. Powdered whey is a nutritional shadow of whole milk. Extracted chlorophyll is a lifeless fraction of green leaves. Lecithin granules are a denatured fragment of soybeans. These various extracts and concentrates are inferior to the whole natural foods they supposedly improve upon. Processing incurs drastic nutrient losses as a result of heat, oxidation, chemicals, and enzymatic destruction. It is correct to say that these foods have been devitalized. Only whole natural foods contain the amount and proportion of nutrients that the body requires. Only whole natural foods are acceptable in a *Hygienic* diet.

## 2. The Superiority Of Raw Foods

Although some foods seem to be rendered more digestible by cooking, it is a fact that most foods are rendered less digestible. Furthermore, any food that is difficult to eat and digest uncooked is not a normal constituent of man's natural diet. Cooking partially or totally destroys the nutrient content of food. Water-soluble vitamins, like ascorbic acid and pantothenic acid, are particularly susceptible to thermal destruction, but it is to some extent true of all vitamins. What may be more important, however,

is the fact that cooking alters the proportions of the various vitamins contained in foods. For example, cooking alters the natural ratio between thiamine and niacin in foods. This occurs because thiamine is readily destroyed by moist heat, whereas niacin is more resistant. Therefore, cooking not only lowers the vitamin content of foods, it also modifies vitamin ratios, which are a very important feature of whole foods.

Minerals may be rendered nonuseable by the body as a result of cooking. A good example of this is the effect that pasteurization has upon milk. The complex organic salts of calcium and magnesium, in conjunction with carbon and phosphorus, are decomposed by heat, resulting in the precipitation of insoluble calcium phosphate salts. These inorganic salts are not assimilable by the body. This is one of the reasons why dental decay has reached epidemic proportions among milk-guzzling Americans.

Cooking tends to deaminate proteins and denature their secondary and tertiary configurations. With the exception of eggs white and certain dried legumes, they are rendered more difficult to digest by cooking. Subjecting fats to heat produces toxic cyclic hydrocarbons and free fatty acids, both of which are highly irritating. Heated fats and oils have been shown, by countless experiments, to be highly carcinogenic. *No informed person will consume heated fats in any form.*

Cooking causes a great loss of the soluble minerals in foods and drives off part of the food into the air as gases (this is particularly true of sulphur and iodine). Cooking softens vegetable fiber which may hamper intestinal motility, and promote fermentation and putrefaction. Although cooking adds to the palatability of some foods (e.g., yams, asparagus, zucchini, grains), most foods are rendered less palatable by cooking, which gives rise to the use of unwholesome flavorings, condiments, dressings, etc.

On the basis of these considerations and others, a diet, in order to be considered *Hygienic*, would have to consist of at least predominantly uncooked foods.

### **3. The Superiority Of Plant Foods**

This category could also be designated the *detrimental effects of animal foods*. All animal products (with the exception of mother's milk) have certain negative features which make their dietary use questionable. Consider, first of all, the effect that animal foods have upon protein consumption. Even modest use of meat, fish, eggs and dairy foods tends to create a protein overload and this is one of the most dangerous dietary excesses. Research has shown that high protein diets actually promote aging and early degeneration. Too much protein exerts a tremendous burden upon the liver and kidneys. It also leaves acid residues in the blood and tissues which must be neutralized by sacrificing indispensable alkaline mineral reserves. The process of aging is characterized by the transfer of calcium from the bones to the tissues, that is, to the arteries (arteriosclerosis); to the optic lens (cataracts), to the ureters (kidney stones), to the skin (wrinkles), to the joints (osteoarthritis), to the valves of the heart (producing valvular stenosis and insufficiency), to the tendons and ligaments (producing frozen shoulder) and to other sites. This, of course, leaves the skeleton osteoporotic, leading to the development of stooped posture, a kyphotic spine, spontaneous fractures and other maladies that are so common to the elderly. High protein diets (due to the accumulation of phosphoric, sulphuric, uric and other acids) accelerate this demineralization of bone and bring about calcific deposits in the soft tissues.

One could argue that nuts and seeds contain as much protein as meats, eggs, etc., and therefore they are as likely to create an excess. However, most people are easily satisfied eating a few ounces of nuts or seeds every day, whereas few people will eat just a few ounces of yogurt. Restaurants serve up to a pound of meat at a sitting, along with other foods. Cottage and ricotta cheese is eaten in huge quantities, even by vegetarians. The simple truth is that animal proteins tend to promote overeating more so than do plant proteins.

The relationship between high protein diets and cancer has been clearly established by studying both animal and human populations. Remember that cancerous cells are characterized by runaway protein synthesis and rapid cellular division. Protein synthesis is accelerated by increased protein intake, so it is

not surprising to discover that cancer bears close tie to excess protein. There is a direct correlation between the amount of protein in the diet and the incidence of cancer on a world-wide basis.

Americans, Australians and West Europeans, who ingest the largest amounts of protein, also have the greatest incidence of cancer, whereas the rural Chinese, the East Indians and native peoples of Latin America have the lowest cancer incidence. This is no casual relationship and it cannot be written off by blaming it on the "stress of modern life."

Animal products are loaded with the worst kind of fat—saturated, cholesterol-laden animal fat. A mountain of evidence has been accumulated relating high animal fat intakes with the development of cardiovascular disease (which is characterized by the deposition of saturated fat and cholesterol in the intimal layer of arteries), and many different malignancies including breast cancer, colon and rectal cancers, and cancer of the liver. Even such diverse conditions as multiple sclerosis and diabetes have been related to the consumption of animal fats. As we have already stated, heated animal fats have been shown to be even more carcinogenic, and considering that Americans take all of their flesh, milk and eggs well cooked, it's no wonder that 1 in 4 eventually succumbs to cancer. Pandemically, those peoples who subsist on low fat, low protein, largely vegetarian, unrefined diets demonstrate the greatest resistance to cancer. The incidence of cancer and heart disease among American Seventh Day Adventists is approximately half the national average. This is quite remarkable considering that only about half of this group are thought to be vegetarian.

Flesh, fish, yogurt and cheese contain various putrefactive products resulting from their bacterial decomposition. Putting partially-spoiled food in the body can hardly be considered a Hygienic practice, despite the arguments of the fermented food enthusiasts. Flesh also contains considerable quantities of the end products of metabolism (like uric acid,) which are held up in the tissues at the time of death. These wastes are poisonous, irritating and burdensome to the body. Considering also that animal products tend to be reservoirs for pesticides, herbicides, and various other drugs and inorganic contaminants, there are many good reasons to avoid using them.

There are just 5 classes of foods that meet all of the criteria established by our three major tenets. These are: fruits, vegetables, nuts, seeds and sprouts. A diet comprised of these foods would abound in every nutrient known to be required, with the exception of Vitamin B-12, and most people apparently can derive enough of this from bacterial synthesis in the intestines. However, we should note that soil bacteria also produces B-12 on the surface of roots, so that adding stringy roots grown in organic soil (with abundant microbial activity) to the diet would constitute a pre-made plant source of B-12 that would be a perfectly acceptable addition to a *Hygienic* diet. Supermarket vegetables would not be adequate for this purpose.

We should note, in closing, that adding some cooked food to the diet (like baked potatoes and brown rice) or limited amounts of animal foods (such as uncooked, unsalted cheese), although not strictly *Hygienic*, may be required in some pathological conditions. Certain people would experience a drastic and undesirable weight loss were they to make an immediate transition to a 100 percent uncooked, all plant food diet. For these people, eating a baked potato now and then represents not a mere compromise but rather a necessary modification of their *Hygienic* regimen. Quoting Dr. Alec Burton, "We must adapt the system to the needs of the individual and not adapt the individual to the needs of the system."

With this acknowledged, let us state in conclusion that a diet, in order to be considered *Hygienic*, would have to consist predominantly (if not exclusively) of uncooked foods of vegetable origin, eaten whole.

### **Article #3: How To Get More Food Value for Your Money By Marti Fry**

If you're like most people you want to get the most for your money. This includes your food purchases too. Many of you have already learned that eating your food raw is the best way to get the most nutritional value from it. Perhaps you've also discovered that your doctor, hospital and prescription bills have gone down (or, hopefully, disappeared altogether).

When you learn that the body heals itself and that drugs, whether they're prescribed by a doctor or sold without a prescription, always harm your body and never help it, you realize that going to a doctor or a drugstore is the opposite course from what you should take.

In the *Health Crusader* you have been learning:

1. which foods are best—fresh raw fruits and non-starchy vegetables;
2. which foods are second-best—dried fruits, nuts and seeds and raw starchy vegetables, (including roots and legumes);
3. which foods are third-rate—lightly steamed starchy vegetables such as yams, potatoes, sweet potatoes, squash, peas, corn, etc. and other lightly steamed vegetables such as broccoli and brussel sprouts;
4. which foods are fourth—rate—lightly cooked rice, millet, etc.; and
5. which foods are worst to eat—all the rest!

Even if the first-rate and second-best foods are more expensive in the store, they are still the best value for your money because they give you the most and harm you the least. Now let's say you eat only top-rate foods and you eat them raw. Is this everything you can do to get the most for your money? No, there's more!

Many of you have already learned that most organically-grown foods contain larger amounts of high-quality proteins, minerals and vitamins than the majority of commercially-grown produce. But there's one more consideration and this is in the area of food preparation.

As you may know, there is a great loss of vitamins and usable protein and minerals when food is cooked. This is the result of two serious occurrences:

1. The food is oxidized, and
2. Lysosomes, which are enzymes within food cells, will self-destruct the food components (carbohydrates, minerals, vitamins, etc.) within the cell.

These two occurrences happen only when the cell walls (or some of the cell walls) are broken, as by heating, freezing, cutting, blending, juicing or mashing. The cell contents are exposed to the oxygen in our air; and vitamins, minerals and proteins chemically combine with the oxygen and are rendered unusable to us in providing the nutrition they're supposed to. Also, the lysosomes go to work to break down the cell components before your body gets a chance to use them.

Be aware that these lysosomes within food cells are destroyed by heat over 120 degrees. They become incapable of any kind of activity, constructive or destructive. But while it is true that raw foods are far superior to cooked foods, the processes of oxidation and enzymic breakdown also come into play when you eat raw foods, but to an insignificant extent.

When the cell walls are burst by methods other than heat, such as by cutting, mashing, blending or juicing, the vitamins, minerals and other food components are destroyed both by the cells lysosomes and by oxidation.

For example, when you bite into an apple or pear many cell walls are broken and oxidation occurs. However, you will get more nutrients from an apple or pear eaten this way than from the same apple or

pear that has been cut up into a fruit salad. This is because many more cell walls are broken, usually for a longer period, when fruits are cut up into a salad. (The same is true for vegetables, of course.)

What's true for cut-up foods is also true for mashed, blended or juiced foods. Blending and juicing break open the protective walls of almost all the cells, in the food, causing a considerable amount of nutritional value to be lost. That is one reason we recommend that you either not blend or juice foods or else do it sparingly. (The other reason is ecological.)

You may want to mash avocados to make "Vegemole," a salad dressing or a dip; or you might want to make a cut-up salad. But in the case of both avocados and other foods you are better off blending, juicing, cutting up or mashing them *only occasionally*—for variety or for guests, reluctant family members, or people without teeth or with other special problems.

So remember, when you are preparing foods a great way to get the most value from your food is to eat it whole. "Finger salads" of whole fruits or vegetables that you don't cut up are considerably more nutritious than cut-up salads. This is because of the oxidation and enzymic action that occur when foods are cut up. Why not eat whole foods more often and get more nutrients for your money and with less fuss and muss?

## **Lesson 28 - The Elixir Of Life: An Exploration Of Food Conditions, Body Conditions, And Eating Conditions That Beget Euphoric Health And Long Life**

- [1. Introduction](#)
- [2. Achieving Natural Life Potential](#)
- [3. Food And Short Or Long Life](#)
- [4. Factors That Shorten Life](#)
- [5. Exercise And Vigorous Purposeful Activity As Life Essentials](#)
- [6. Mental And Emotional Factors In Living A Natural Life Span](#)
- [7. Happiness, Enjoyment And Pleasure As Factors In Realizing Life Potential](#)
- [8. Questions & Answers](#)

### **1. Introduction**

To set the correct perspective for this lesson it is wise, at the outset, to point out there really is no elixir of life except by comparing normality with the low standards of life prevailing. There is no such thing as long life—that is, no one can outlive the human potential. There is the human potential and anything short of that potential must properly be called shortened life. This potential is better called the natural or normal human life span and anything less than the realization of the normal human life span is premature death. Mature death is a natural death, a death resulting from the simultaneous cessation of life activities by the body's major organs. It is painless and free of suffering.

This lesson concerns itself with the touchstones that assure health, the necessary conditions of a normal life span. The lesson also examines the abuses heaped upon the human body that cause loss of health and thus shorten life.

#### **1.1 The Idea of an Elixir Vitae**

Legends of elixirs come down to us from prehistoric times. Undoubtedly the idea of elixirs was spawned by shamanism. Shamanism was a generalized practice of ministering unto human aspiration and credulity. Shamens were medicine men and theologians rolled into one. Their craft and livelihood depended upon exploiting the human propensity to believe and trust. They thrived by foisting upon those they "served" magic healing potions which find their counterparts today in Pharmaceuticals (magic weeds) and herbalism. They allayed inquiries into human origins and destinies by fabricating new belief systems based upon legends and rituals that commanded homage of the times. This arm of shamanism evolved into the priesthood while the other arm evolved into what is called medicine.

Stories of long-lived peoples circulated for there were, indeed, peoples who lived long, relatively, in certain areas of the world. Shamens, who were really extraordinary confidence men, took advantage of this wish to believe, this hope for long life, by attributing long life to substances which had curative

powers. Hence anything that, in reality, drugged the human constitution was credited with curative virtues and could have been a candidate for use as an elixir vitae.

Water with toxic minerals early came to be regarded as an elixir vitae. Drinking of these waters and bathing in them were supposed to furnish the curative powers the body needed for good health and long life. To this day, many waters are regarded as curative of human ills and possessed with the power of conferring long life.

Many shamen promoted their brews and concoctions as curative and capable of conferring long life. These brews were generally concocted from herbs which the shamen jealously guarded as trade secrets. Somewhere in murky prehistoric times came the idea that rejuvenation could come from eating analogous parts of animals. If sexual powers were to be resuscitated, the eating of animal testicles were thought to restore male, sexual prowess. Eating of brains was thought to restore mental powers, and so on. Today these voodooistic ideas have their counterparts in so-called glandulars.

In early history, alcoholic spirits came to be regarded as elixirs. Anything containing alcohol was a curative agent and also a substance that conferred long life. The idea that alcohol was a curative agent survived well into the 19th century and the belief's vestiges remain today.

In the middle ages, alchemists, sought philosopher's stones and new chemicals with which to transform base metals into gold or silver and with which to restore health and perpetual youth.

In the age of exploration, courageous men blazed new pathways in uncharted lands in search of the fountain of youth and fabulous foods with curative powers that would confer long life. Ponce de Leon was such an explorer who discovered Florida in search of a fabled fountain of water in Florida that would cure ailments and confer perpetual life in a youthful state.

Today we have many laboratories searching for an elixir vitae to give humans long life. Many concoctions have been hailed as elixirs. One of the foremost is procaine (same as novocaine), popularly called Gerovital, meaning, literally, long life. That long life can proceed from the employment of any substance while the causes of shortened life are indulged in, of course, impossible. No substance can confer long life in the first place.

The priesthood arose when a certain class of shamen assumed the role of intermediaries (favored or privileged representatives) between the gods and beleaguered humans. Their role was to curry favor with the gods by direct intercession on behalf of ailing clients. At least that is what they had the sufferer or long life seeker believing. They performed rituals and incantations in behalf of those who subscribed to their services. Those who stuck with administrations of "magic weeds," brews and concoctions were the precursors of today's medical practitioners.

Simply stated the idea of an elixir of life springs from *hopes* for long life. The wish is father of the belief.

## **1.2 Examples of "long-lived" peoples**

For the past two thousand years the Bible has spoken of very long-lived people, including Adam and Eve. Methuselah is said to have lived 969 years. But these ages become immediately suspect when we learn that women were said to have had their firstborn at ages ranging from 120 to 200 years. In those times, as today, many centenarians lived quiet, frugal lives in certain areas of Eastern Europe and in Western Asia. Travelers brought news of these people and many legends arose about their existence. Just as we have one-track minds today, then, answers were sought for this remarkable longevity in some food, substance, ritual or other single practice.

## **1.3 Examples of possibilities for "long" life**

In most countries of the world there are those who have surpassed a hundred years of age. Their

longevity has excited much curiosity and inquiry as to their "secret." Even to this day an outstanding practice of a centenarian is searched for to account for extraordinary longevity. If the oldster is a wine drinker, the wine is likely to be characterized as responsible for the longer life. The fact the oldster breathes, sleeps, is active, eats frugally, etc. is likely to be ignored. Why shouldn't geriatric personnel emphasize as elements of longevity those life factors that everyone possesses? There must be some "secret" factor.

## **1.4 A Correct Perspective on Longevity**

That humans have a natural life span potential of 140 years to 160 years is rarely taken into consideration. The yearnings of most for long life are becalmed by the promise of eternal life—not here but in the hereafter. Long life does not become important here if it is but the prelude to eternal bliss in another paradise.

Biologically, humans have inherent faculties that will carry them well past the century mark. The weakest organs of the human body are the kidneys and they have a life potential of 300 years or more according to geriatric specialists. Some long-life specialists feel the human organism is so perfect there's no reason it should ever die. Of course, the view does not take into account the limits of cell regeneration.

In view of the fact that there are societies in which oldsters reach well past 100 years of age and that authenticated life spans well past 150 years of age exist, there is no denying that humans can live past 100 years of age. Inasmuch as most creatures in nature live five to eight times the age of maturity which is, in humans, about 22 to 25 years of age, and inasmuch as humans have lived longer than 150 years, then it is quite logical and scientific to conclude that humans are normally endowed with a life *potential* of about 150 years.

Thus it becomes apparent that those who live their life potential are not long-lived but that, on the contrary, those who do not achieve their life potential are short-lived! The inquiry thus takes on a new perspective. The search then comes to embrace not only those factors that assure achievement of life potential but those factors that are destructive and, as a result, shorten life.

[Home > Lesson 28 - The Elixir Of Life: An Exploration Of Food Conditions, Body Conditions, And Eating Conditions That Beget Euphoric Health And Long Life > 2. Achieving Natural Life Potential](#)

## **2. Achieving Natural Life Potential**

Our study now must turn more to those practices which cause premature death as well as the delineation of those practices normal to our being which assure realization of natural life potential. Your clients will expect your guidance not only in matters of health, but also as an "authority" in related matters, longevity being one of them. This lesson is designed to make you competently conversant with the subject.

### **2.1 Causes of Shortened Life**

In a word, life is shortened in humans when deviation from our biological heritage occurs. Just as the engine life of a car will be shortened by wrong fuels, poor maintenance and abusive use, so too will our bodies become clogged and disabled by wrong foods, improper life practices and applications that deplete energies and faculties. Just as the engine is designed to operate under certain conditions, so too has the human organism developed within certain adaptational parameters. Anything that impairs health

also shortens life.

## 2.2 Primary abuses of modern humans

Unfortunately, human abuse begins before conception. Degenerated men and women conceive in bodies that are almost invariably wracked by the ravages of unceasing toxicosis. While healthy by the pitiful norms of our society, very few parents-to-be have even a modicum of health.

During the fetal period, mothers are likely to get little if any exercise, eat of fare unfit for man or beast and indulge in many toxic habits that are endemic to our country. Moreover, mothers are likely to be drugged frequently in many ways, especially by their physicians. Births are especially fraught with dangers for both mothers and infants because of the "manipulative" drugs employed for hospital/physician convenience. Every antivital act against mother and infant impairs both, undermines health and shortens life.

As likely as not, the baby will be put on some formula that will fail to yield nutrients—formulas are even worse than the milk of diseased mothers.

After babyhood with indisposing and unwholesome formulas, baby usually undergoes introduction to a plethora of unwholesome foods. Junk foods make an early appearance in baby's diet. Unnatural animal products, meats, and cereals are likely to be added to baby's diet at from two to four months. These should never be in anyone's diet in a whole lifetime but, even if they were normal items of human diet, baby shouldn't be fed anything other than mother's milk until the time teeth have erupted. Of course, a mother who cannot lactate must either secure the services of a wet nurse (second best), or feed baby raw goat or cow's milk (third best with goat milk being the better of the two) along with a diet of *freshly* expressed fruit juices. Inasmuch as sweet fruits undergo no digestion, their sugars are absorbed as they are by baby. Fruits that are well-prepared may be fed to baby but only as a last resort. Fruits, animal milks and nut milks are superior to commercial formulas.

Almost all youngsters suffer the many "usual childhood diseases" because they have been subjected to many usual childhood abuses. All impairing factors, it bears repeating, undermine health and shorten life.

Early in life, youngsters are introduced to corrosive beverages, fried and cooked foods, condiments, side-stream cigarette smoke and a host of other debilitating influences. As likely as not, youngsters will be corralled via the automatic babysitter known as a television set. Instead of becoming active and participating in life, instead of developing and becoming educated and trained in life's activities, most children are becoming passive misfits. The tragedy of the situation is highlighted by two research projects conducted by a sample of noted physical fitness expert, Bonnie Prudden. In 1954, she tested a sample of our youngsters and found that a shocking 58.6% could not pass a minimum physical fitness test. In 1978, she again made the tests. This time a shocking 86.2% could not pass the same test! If that does not point out the direction in which we're travelling, the gravity of the problem and the herculean nature of the task before you and other health-aware people, then it's not likely that anything else will. The tragedy of our children is a national tragedy—a worldwide tragedy!

## 2.3 Healthful Living as the elixir vitae

That long life can be achieved only by healthy people should be self-evident. That those perpetually encumbered with impairing influences resulting from unhealthful practices cannot survive as long should be equally self-evident. Thus it becomes obvious that humans can realize their life potential by living healthfully and that any deviation will result in suffering and shortened life.

Healthful living involves touching base appropriately with every need of life in all aspects of our being. Our basic requirements are as outlined in the earliest lessons, i.e., pure air, pure water, adequate sleep and rest, sunshine and natural light, foods of our biological adaptation, vigorous activity, temperature

maintenance, pleasant environment, a nondistressing lifestyle, belonging to a group of similar disposition and so on.

## **2.4 Outdoor Life essential to best health**

Almost every long-lived person of note has worked out of doors in gardens and orchards. Being a gardener myself, I can assure you that nothing overcomes stress so quickly as a half hour to an hour's work in the garden. Reestablishing identity with the basic environment and its providence becalms as nothing else can.

Encourage those whom you serve to start gardening, taking walks and hikes in the country or undertake other activities that give them more fresh air, sunshine, exercise and identity with nature. Just as plants that have their roots with earth mostly severed wither and die, so too do humans suffer when they lose touch with those fundamental requisites of life. Just as nonuse of body parts are abuse, so too is the loss of touch with the outdoors and warm congeniality with peers abuse.

## **2.5 Living in a distress-free environment**

Perhaps it is incorrect to say we should live in a stress-free environment inasmuch as our superb human adaptations have been spurred by stress—by the need to cope. However, distress consists of situations and events with which we cannot cope or which impose great difficulty upon the organism. Continuous distress will speedily exhaust the organism and contribute to its early demise.

In our society the greatest distress arises from our peculiarly rapacious economic system that keeps most of us in more or less constant insecurity. Assurance of life and its means exists for relatively few Americans, even for the affluent. In an exploitative society few have situations that are so secure that distress does not occur. Even those who have ideal situations are potentially distressed by the plight of their brethren. Perhaps no people on earth are more insecure than modern day Americans.

## **2.6 Rejuvenating measures and influences**

An assessment of life and its possibilities in a somewhat detached objective manner establishes a perspective that makes most of our problems trivial. For example, if you've read astronomy and you imagine the vast reaches of space, our personal affairs and problems are small in that light, though, subjectively, the whole world revolves around us and our concerns.

Helping establish a philosophical outlook upon the world and the foibles of humans will enable many to better conduct their lives. When we can view most of our brethren objectively as being weak creatures given to inconsequential and dissipating activities for the most part, that gives us the impetus to tune ourselves in with nature and saner peers—to make ourselves more virtuous and exemplary.

Imbuing our lifestyle with the basic essentials of life heretofore presented will enhance health and life expectancy. Perhaps the most important of the essentials is belonging to a peer group. Humans are gregarious and mutual appreciation among peers establishes the condition upon which all can thrive.

Basically, ailing clients can be turned around by such simple steps as fasting, reorienting their lifestyle to include the requisites of life in their best form, and unburdening them of debilitating practices. But the problem usually always extends to the emotional, social and economic planes as well. *Hence a philosophical overview should always be explored with clients.*

Get clients physically, socially and emotionally active on constructive courses that establish their basic rapport with nature and a peer group. Get them involved in activities such as gardening, hobbies and crafts, etc. that bring their innate human drive to fruition in creativity and meaningful service.

A study of the world's healthiest and longest-lived peoples reflect a society of individuals rather secure in the needs of life. Sharing, mutual reinforcement and assurance from a peer group does not create the

distress and insecurity as exists in exploitative societies.

America is a highly exploitative society wherein few deep and abiding friendships exist. You will find it difficult to help your clients order their lives in contravention of an aggressive economic system that is by its nature divisive. Most healthy and long-lived peoples are close to the land and nature. They secure their livelihood directly from the soil—from Nature. They live in harmony with their relatives and neighbors—they have a society that does not continually assault them with demands that stress and strain them.

The most constructive steps you can assist clients with are in reorienting their living practices to healthful ones. Secondly, you can set forth the many influences you note in their lifestyle that tend to distress them and cause problems on every plane of their being. The nineteen essentials of life cited and elaborated upon in Lessons 3 and 4 should be taught to every client so that understanding of their importance is assured. Guidance and suggestions as to how these needs of life may be implemented should be undertaken, tailored as much as possible to the peculiar needs of each client.

The most immediately rejuvenating and healthful changes you can effect in clients' lives involve guiding them to fasting, vigorous exercise and an all-raw diet consisting preponderantly of luscious fruits with a few vegetables, nuts and seeds.

Always keep in mind that, as a practitioner of Life Science, you must strive to imbue your clients with a knowledge and understanding of their needs in every facet of life that bears upon their welfare.

## **2.7 Advantages of a community of peers**

Consciously and unconsciously, in accord with our needs, we all seek the comfort and assurance of life and its means upon reasonable expenditure of physical labor. We seek this amongst those whom we recognize as peers—those with interests and disposition largely paralleling our own.

Establishing identity and standing in a peer group is difficult within the context of a society that places values upon individual economic achievement and standing rather than upon the humanness of merit of every individual. When clients are brought to the realization of the conditions of our society—when they can be imbued with a philosophical overview of their circumstances so that they can better understand and cope with it, than the bases for a less stressful and debilitating existence has been established.

Many individuals of my acquaintance have joined in communities with individuals of similar interests and drive. The experience of facing the world with others rather than facing its imposing awesomeness alone has reawakened their will to live and given them new ambitions and drives. Nothing rejuvenates, enlivens and renews life so effectively as a community of peers who live in cooperation and harmony.

[Home](#) > [Lesson 28 - The Elixir Of Life: An Exploration Of Food Conditions, Body Conditions, And Eating Conditions That Beget Euphoric Health And Long Life](#) > 3. Food And Short Or Long Life

## **3. Food And Short Or Long Life**

Even though there are many debilitating influences that prove detrimental to our populace and cause our brethren much suffering, nothing looms so large in individual degeneration as dietary practices. In no other area do we flaunt our biological disposition so flagrantly. Therefore it is appropriate that you become steeped, in nutritional science and concern yourself most intimately with the feeding practices of those whom you serve.

### **3.1 Food—Our area of greatest deviation from natural norms**

Of all the human deviations from correct biological observation of our needs, no perversion is so deviant and destructive as that which Americans undergo in their dietary practices. Our physiologically correct diet as frugivores is a diet of fruits eaten in the delicious ripe raw state. Many of us are deficiency minded and feel the fruit diet inadequate even though it is not. To quell such feelings, the addition of a few vegetables, nuts and seeds adds an extraordinary amount of vitamins, minerals, essential fatty acids and proteins to nutrient intake. Not that fruits do not supply all our needs and better, it's just that a psychological need is met. What do we find our brethren eating? What contributes to their pathology more heavily than anything else?

- A. About 45% of the average American's caloric intake consists of fats. Most of these fats have been heated, fried, chemicalized, refined and otherwise rendered harmful, even carcinogenic. Humans are not a species of fat food eaters. In fact, fats are handled rather poorly even in their best natural form as in seeds, nuts and avocados. Untold pathology results from this eating proclivity including obesity.
- B. A substantial amount of the American diet is of animal products including meat, milk and milk products. Most of the American intake of fat is involved with animal products. Humans who eat products derived from animals are indulging in the most pathological of the perversions for, in addition to being biologically wrong in its fresh raw state, it is even more disease-producing in its processed, fried, cooked or fermented states.
- C. The average American partakes of cooked foods. All cooked foods, to the extent they have been cooked, are deranged and fail to supply nutrients to the extent they have been degenerated. As Professor Kouchakoff of Switzerland demonstrated in the late 1930s in over 300 carefully conducted experiments, cooked foods beget pathological symptoms within an hour or two of eating, especially leucocytosis.
- D. The average American has many poison habits, among them being a predilection for salt, pepper, vinegar, spices, peppers, seasonings, dressings and other toxic and pathological condiments.
- E. Most American adults indulge in one or more drug habits. Prominent among these are coffee, alcoholic beverages, theobromine, theine, beverages containing caffeine and other toxic additives, flavorings, colorings and stimulants, tobacco, etc.
- F. Most Americans eat breads and other grain products to which we are not biologically suited to cope.
- G. Beans and other legumes form a significant part of the American diet. As eaten, legumes (including peanuts) are pathogenic. This is readily evidenced by gassy emissions and indigestion.
- H. Raw fruits and vegetables comprise about ten per cent of the American diet but many eat heavily of fruits and vegetables while many others eat little or none. While fruits and vegetables comprise a much larger percentage than this, most of them have been so deranged by cooking, processing, canning, etc., that they are pathogenic rather than life-enhancing.

### **3.2 Biologically correct foods eaten raw are true elixir**

There are no real elixirs. There are no miracles. There is no magic. There is normal and abnormal—right and wrong. Because most Americans are so addicted to wrong habits of eating, a return to natural and normal eating practices results in such dramatic improvements as to be proclaimed miraculous. Our natural dietary consists of delicious fruits. All else is deviant and either less than ideal or downright pathogenic.

For our purposes, we may regard the fruitarian regime the elixir of life, but only because this is the greatest single improvement that can be made in our lives.

In getting clients on to the fruitarian diet, you can suggest that they try a purification diet. Of course this is merely an semantic entree, for they'll soon enough learn that fruits do not purify or cleanse the body per their reputation but that, on the contrary, they are handled so efficiently that more body energies can

be devoted to cleansing and healing. Fruits do not yield up toxic debris which other foods do. Hence the results of fruitarianism are true rejuvenation. Fruits are the true elixir of life insofar as there may be said to be one.

### **3.3 Cooking among worst treatments of our food**

Among the worst curses Americans have visited upon themselves is that of cooking. Not only is it a gross evil in itself but it is often the agency that makes palatable that which should never be in the diet in the first place.

These are two primary evils that cooked foods wreak upon our bodies:

1. Foods that have been partially, mostly or wholly destroyed and deranged by cooking deny needed nutrients to the body. Heat has altered nutrients so much the body cannot make use of them.
2. Nutrients that were formerly usable have been transformed into coagulated, caramelized and inorganic debris that not only cannot be used, but which are toxic and pathogenic.

A host of other evils flow from cooking which in large measure destroy our human potential for health and longevity.

### **3.4 Toxic fare—Condiments**

If cooking may be said to ruin our foods, condiments are ruined even if eaten raw. The American proclivity to use stimulants and flavor modifiers is rank, rampant and pathological. Foremost among the condiments that help destroy health are salt, herbs, spices, pepper, vinegar, gravies, dressings, sauces, seasonings, etc. The ingredients which vitiate the human intestinal tract and body are:

1. Oils and fats. All refined and extracted oils and fats, from whatever source, whether raw or cooked, are unwholesome in the human diet. If cooked, their hydrocarbons are carcinogenic.
2. The "acid kick" sought by most Americans because of their jaded palate is usually realized by adding vinegar to foods or condiment concoctions. Vinegar partially or totally vitiates food digestion. As bad as the food may have been, indigestion is far worse. Little enervates so much as poor digestion. Every case of indigestion worsens health. Even lemon juice combines so poorly with most foods that it ruins digestion.
3. Herbs added to foods or condiment concoctions (recipes) are toxic in themselves. What we call herbs today are not eaten for their food value but for their excitation of the taste buds. Peppers, spices, basil, onions and garlic, chives, mints, paprika, bay leaves, oregano and a long list of other agents are toxic in themselves and contribute to poor health by themselves no matter how eaten, cooked or raw. Some of the foremost toxic elements of herbs are capsiicum and cayenne from peppers, and allicin and mustard oil from garlic, chives, onions and lily family members. All herbs have some poisonous component.
4. Salt, the foremost condiment, offers not one virtue. It is indigestible. It is absorbed as salt, held in a briny solution as salt (the body then needs extra water to retain this salt), and is excreted as salt. Not only can the body not digest and make use of salt, but this pernicious substance destroys cells and fouls up vital body processes. A tablespoon of salt eaten on an empty stomach is enough to kill most people outright.

### **3.5 Toxic fare - recreational drugs**

While condiments may be said to be recreational drugs because of the "kick" they give, there are drugs partaken of strictly for their kicks. Among these drugs are tobacco, alcohol, coffee, chocolate, teas, sodas, beverages, marijuana, cocaine, opium, heroin and other so-called hard drugs. Drugs prescribed and nonprescribed are often taken as recreational drugs. Among these are tranquilizers, amphetamines

and so on.

Americans often lament why so much misfortune and suffering should befall them. While making their utterances, they are often active in some drug habit that is contributing heavily to their problems.

### **3.6 Toxic fare - wrong foods**

Anything put into our bodies other than that to which we as frugivores are physiologically equipped to handle is more or less toxic fare. It is either toxic of itself or it is of such a character as to pose difficulties that lead to enervation and toxicosis.

The dietary errors of our times embrace both types of violations—not only is wrong fare usually intrinsically toxic, but also burdens the system so much that enervation results as well.

Foods which we do not digest well tax the system and lead to an enervated state, especially when these foods interfere with or prolong sleep as they often do. Troubled sleep denies us regeneration of normal nerve energy.

Ordinary cow's milk, for instance, which is touted as such a perfect food, is quite toxic in the average human intestinal tract because we do not have the enzymes rennin or lactase with which to digest it. Thus lactose and casein are toxic themselves and, because of bacterial breakdown, beget toxic by-products.

Most foods of today have been cooked, preserved, processed and prepared in such a manner as to either add and/or create toxicity—not that they wouldn't have been good foods in their natural state.

Potatoes, for instance, are a third-rate food—still quite high on the scale, with very conservative cooking. But, with the addition of heated oils in cooking, they become rather saturated and indigestible.

Both the oil and the potatoes thus become sources for pathogenic substances.

### **3.7 Haphazard food mixtures generate toxic products**

Combining foods indiscriminately often involves meals of incompatible foods. Most Americans eat sweets, proteins, fats and starches at every meal. Statistics show that over half the meals eaten in America result in intestinal discomforts due to indigestion.

When indigestion occurs, bacteria take over and decompose the various food components. The byproducts of bacterial decomposition are quite toxic, these being acetic acid, lactic acid and alcohol in the case of carbohydrates and ammonias, purines, skatols, indoles and other deleterious substances in the case of proteins and yet others in the case of fats.

When the foods eaten in bad combinations should be omitted from the human diet even if eaten alone, the situation is worsened.

The perpetual assault upon human well-being from this source alone is enough to create considerable pathology and shorten life.

### **3.8 Guidelines for more nutrients and less toxicity from eating**

The more foods we consume of our biological adaptation, the more nutrients we derive. Foods which we are biologically equipped to efficiently handle are readily digested and their nutrients swiftly absorbed. They offer no toxicity inasmuch as our digestive enzymes breakdown every component that could offer problems. Fruits are the only category of foods that fill this bill ideally.

When we eat ideal foods in an uncomplicated manner, we obtain their goodness and create no problems. This is conducive to health which is a prerequisite to prolonged youth and long life.

## 4. Factors That Shorten Life

Dr. Georgi Z. Pitskhelauri is a Russian gerontologist who has been researching those factors responsible for the long life of Abkhazians and others living in and around the Caucasus mountains. His studies show that centenarians:

- do not smoke—in fact, only a few smoke at all.
- do not drink alcoholic beverages to any extent—their primary drinking is a few sips of wine prior to mealtime.
- do not ordinarily eat before noon.
- sleep eight to ten hours daily.
- are very active, doing almost all their work out of doors.
- sleep out of doors for most of the year.
- their foremost foods are grapes and citrus with other fruits being a good part of their diet also. Vegetables in salads constitute a substantial part of their fare.
- animal products were sparse to nonexistent in their diet.

Dr. Pitskhelauri reports this in such a way it is clearly obvious that:

- smoking is life shortening.
- alcoholic beverages shorten life.
- morning meals are not healthy.
- inadequate sleep is not conducive to long life!
- lack of activity will deteriorate the body.
- being cooped up indoors away from fresh air and natural light shortens life.
- animal products are not healthful in the diet.

Those factors which shorten life seem to predominate in our society. Thus it behooves you as a practitioner to recognize those influences which destroy health and bring on early death. While these life-sapping factors are multitudinous, they are easily recognized for their anti-vital character. Let's explore some of them.

### 4.1 Polluted air

Relatively pure air is our foremost need of life.

It has been said that the world's air has been contaminated to some extent. Penguins at the South Pole have been found to be contaminated somewhat by particulates generated thousands of miles away in industrial complexes.

Even though pure air may be impossible in today's world, we are able to breathe much better air overall by taking a few steps to better the air quality in home and workplace. Outdoor work and outdoor sleeping are two measures that will vastly improve the quality of the air we breathe. Further, the light we'll be using will be from the sun. Natural light is wholesome whereas artificial lighting of all types is less wholesome.

We have had lessons dealing with the subject of air and the multitude of pollutants that beset it in homes and cities. I suggest that you review these.

While our nasal and lung faculties have a certain capacity for purifying air, it is a talent best little employed. Certainly it is debilitating to continually assault this capacity with heavily polluted air until these faculties are destroyed. *Pure air is essential to best health and to long life.*

## **4.2 Vitiating Social Environment**

On the obverse side of a congenial and assured social environment of peers is perhaps the most demoralizing influence of all. In a condition of strife, bickering, lack of mutual appreciation, economic insecurity, aggressive and exploitative individuals and groups, humans wither. This leads, of course, to enervation, disease, suffering and early death. The social and economic situation must be one where the means of life are readily available for reasonable efforts. Where the products of one's labors are consumed in a community of peers—where relative sufficiency and stability exist within the social group with which one identifies, gregarious, creative and constructive tendencies are met. We feel useful and a part of our environment rather than a consuming/nonproductive member.

Our social situation more than anything else generates positive or negative emotional states. Negative emotions destroy us whereas reinforced and positive feelings are a prerequisite of well-being.

## **4.3 Economic factors that distress the organism**

An adverse social setting is perhaps the most demoralizing and debilitating influence, and economic conditions are usually the soil from which social situations develop. Of course this can be good to bad.

Most Americans are perpetually distressed by earning less than will satisfy their wants. An exploitative society strives to create an even greater market for its products. The promotion of products somehow imbues most people with the idea that happiness can be realized if they have I this and this and that. This unceasing quest for more and more mirrors the basic unhappiness of most of American society's members. The propaganda of commercial promoters drives us to seek happiness in possessions.

Further, the nature of the economic system can be most vitiating. Ours has often been characterized as "a dog eat dog" system. Competitiveness has driven many to play the game viciously. People who are by economic circumstances forced to work in an atmosphere of maximum production and minimal pay feel the injustice. In turn, this gnawing sense of revulsion and resentment is a cancer upon emotional well-being that leads to physical debility.

The longest lived peoples in the world are largely self-sufficient. They live mostly on their own products, yielding little if anything to "bosses," landlords, owners, stockholders, etc. Their life is generally simple economically. Simplification of lifestyle leads to economic independence which is often a key factor in exuberant well-being and long life.

## **4.4 Environmental hazards to life**

In addition to polluted air, vitiating social and economic environments, we may be subjected to life-sapping forces from our working and living environment of which we are little aware. These may be summarized briefly as:

1. noise or sonic pollution.
2. drab, depressing and unaesthetic living conditions.
3. use of chemicals and unnatural substances in workplace and home.
4. polluted water...fluoridated, chlorinated, contaminants, etc.
5. polluted food due to insecticides, chemical residues, other impurities not due to processing, preserving, cooking, etc.
6. physically hazardous working and living conditions that dispose to injuries, even fatal ones.

Ferretting out the multitude of unwholesome influences that debilitate clients can be an onerous task.

Informing your client of the many possible disturbing and dangerous elements in his or her surroundings may enable the individual to remove himself from subjection to them. On the other hand, they may not be able to free themselves from unwholesome influences and a knowledge of them may cause a worrisome preoccupation and unconscious sense of danger that amounts to the reverse placebo effect. The reverse placebo effect is the belief that harm is being done which becomes so depressing as to be harmful. It is the power of negativity that affects us deleteriously.

Ideal in the human environment are natural influences that we identify as supplying the needs of life. Trees and plants, especially food-producing ones, are aesthetic and life-enhancing. An environment that is totally bereft of our natural values as might be found in buildings, streets and alleys have adverse influences upon humans. Deeply inherent in humans is our pristine place in nature and the negation of its salubrious influences destroys the qualities and values needed for healthful living and long life.

Many of us in both home and workplace have chemicals, oils and soaps coming in contact with our hands and other body parts. Needless to say, anything that is not normal to the body can cause derangements that detract from health. Any chemical or toxic material that interferes with vital body activities at any point can cause many pathologies including cancer.

Working and using unsafe equipment often inflicts little cuts, abrasions and bruises upon clients. All such injuries are life-sapping and take their toll upon us.

When dealing with clients, survey their entire lifestyle in the search for factors that contribute to human suffering.

[Home](#) > [Lesson 28 - The Elixir Of Life: An Exploration Of Food Conditions, Body Conditions, And Eating Conditions That Beget Euphoric Health And Long Life](#) > 5. Exercise And Vigorous Purposeful Activity As Life Essentials

## **5. Exercise And Vigorous Purposeful Activity As Life Essentials**

Inactivity is characteristic of the nonliving while purposeful activity gives evidence of life. Inactivity other than that needed for rest, relaxation and sleep tends to atrophy our minds and bodies. From infancy, humans should be involved in numerous activities that develop mental and physical faculties.

Unless we experience vigorous activity in our work, hobby or recreation, a vigorous program of contrived exercises is essential to well-being. Constructive activities that daily exercise most or all the body's parts are most desirable. Gardening, work and pursuits that involve lifting, stretching, shifting, accelerated breath and pulse are, as a rule, health-building.

Even though we may be involved in activities that develop our muscles and mental acumen, it is still desirable to take brisk walks or runs that build and maintain endurance. The many benefits of running alone are innumerable—they're still being discovered and catalogued. In short, *life is activity* and you'll do well to encourage and foster it in the lives, of those whom you are privileged to touch.

### **5.1 Vigorous activity as a rejuvenator and fountain of youth factor.**

When we examine the vast literature on exercise, we encounter a wealth of evidence that highlights its enormous benefits. Vigorous activity's role in fitness and well-being could be ranked among the top three essentials of life though, in reality, it is not as vital as many other life factors. But, unless heavy physical activity is a part of an individual's life, health will be lost and a much shortened life will result. Thus regular and vigorous activity is absolutely essential to healthful living and long life. Without it,

neither will be realized.

Dr. Cureton of the Physical Fitness Laboratory of the University of Illinois made perhaps more experiments with exercisers than anyone else. His findings related to the benefits that exercise bestows read like finding a pot of gold at the end of the rainbow. There are many rewards and everyone can share them, even handicapped persons. Among his many noteworthy contributions to the science of physiology is the discovery that, by the age of 25, the average American has lost 25% of his capillary circulation fitness and, by age 35, 60%. This is tragic, of course. Poor circulation results from lack of usage of musculature. The relatively inactive lives we lead account for this.

Energy and health decline with declining circulation. Poorer sleep, posture, digestion, chronic fatigue, increase in ailments, our disposition and a general decline characterize *inactivity*. It bears repeating over and over that one must either "be fit or be damned." It is easier for a camel to pass through the eye of a needle than for an inactive person to be healthy and long-lived.

There is a silver lining to this typical American predicament. Through fasting, proper diet and exercise program, and observance of the other essentials of life appropriately, almost everyone can be rejuvenated unless the powers of life are almost totally lacking.

Perhaps a personal observation is in order. When I was in New York, an associate had a son who was only twelve and tipped the scales at about 180 pounds. I was told this obese boy who stood only five feet five inches tall had two interests in life—eating and watching TV. This boy was shipped to summer camp for two months in the Catskills where he was among over fifty other boys. He was given chores to perform. He was put on a mostly vegetarian diet and permitted only three meals a day. He hiked, ran, played volleyball, baseball and other games vigorously. He did this daily for two months. Can you imagine his parents' surprise and delight? During these two months, their son increased in height two inches and lost weight down to 130 pounds. He had developed both curricular and athletic interests and wanted to become a professional baseball player. From thereon in life he thrived and today, more than twenty years later, he is a successful businessman who is an superb example of physical fitness.

Most of your clients will be of more advanced years than this but the benefits of exercise can be realized in nearly everyone—they're just slower in coming. You can be instrumental in rescuing many from a kind of hell of their own making and involving them in vigorous activity will be one of your primary tools.

We are fond of pointing out the immense benefits of fasting. Vigorous activity also yields many salutary benefits and, coupled with fasting and other salubrious practices, will rebuild anyone that has the spark of life still remaining.

To illustrate this, there are cases of retirees who have recharged and rejuvenated themselves. A few years back, an 88-year-old woman entered and finished a marathon, beating out women who were in their forties and fifties! She had not even begun to run until after eighty years of age!

Never underestimate the power of exercise to turn a client's life around. And of this you can be sure: *you'll meet very few who get enough vigorous physical activity.*

## **5.2 Exercise alone as a healthful activity insufficient**

How many articles have you noted of athletes dying of heart conditions, cancer and other problems? There are many. In recent times I've read about an 18-year-old star athlete in Bastrop, Texas, dying of a coronary. I've read of a football player only 20 years old at Southwest Texas State in San Marcos having serious cancer. I remember the famous coach, Fairchild, of the University of Oklahoma, dying at age 37 of cardiovascular problems. The same thing happened to a professional football player for the Detroit Lions.

These men were extraordinarily fit because of their exercise and heavy activity. But they were filled through and through with the ravages of chronic toxicosis. While exercise is a very healthful measure, it

is not a cure-all for heavy meat-eating, heavy drinking of alcohol or soft drinks, or the use of other toxic fare.

Thus we get warning after warning from physicians to "take it easy" when obviously exercise is required. They often tell us exercise can kill. The truth is that exercise is rejuvenating, life-restoring and life-extending. Persistence in life-destroying dietary and poison habits is what sabotages and kills the body, not constructive habits. At worst, vigorous exercise can be the agency that puts the body to the test which it fails. Chronic toxicosis is the culprit, not the exercise. Other healthful measures must be taken in conjunction with an exercise program.

### **5.3 Constructive activities that assure long life**

Every life essential must be appropriately observed. Some of these life essentials are rather nebulous, especially as they relate to emotional and mental factors.

The basis for healthy emotions and an admirable mental disposition is born of all the other factors of life. The sense of belonging, expression of the creative and procreative urges and security of life are essential to our emotional and mental well-being.

With clients you should search out environmental and social factors that destroy well-being as well as ascertain these that build well-being. Very frequently you'll find a dearth of influences that build confidence, self-reliance and other attributes of well-being.

You should encourage your clients to develop a hobby. Few pursuits can be as uplifting as organic gardening and orcharding. Not only do they furnish wholesome food, but they also involve the individual in vigorous, creative activity, self-reliance and self-assurance, and they yield a plethora of other benefits.

Encourage your clientele to get deeply involved in some hobby that keeps them physically active, draws upon their creative talents and furnishes them appreciable rewards.

[Home](#) > [Lesson 28 - The Elixir Of Life: An Exploration Of Food Conditions, Body Conditions, And Eating Conditions That Beget Euphoric Health And Long Life](#) > 6. Mental And Emotional Factors In Living A Natural Life Span

## **6. Mental And Emotional Factors In Living A Natural Life Span**

We humans have a tendency to be very upset if the world does not go as we want it to without considering how realistic our expectations and wishes are. Pleasant emotions are essential to health, but nothing will undermine overall well-being so quickly as distressing emotions.

Emotional states are our responses to life situations born of our disposition, most of it beneath the level of consciousness. Emotional responses reflect our maturity and bearing.

### **6.1 Self-mastery essential to emotional equilibrium**

Unless we have developed a framework of a philosophical overview—one that gives rise to reflection and a deliberately charted course in our affairs, we're likely to be buffeted by the winds of every emotion that arises. Emotions arise as responses to situations—they are mechanisms for dealing with external affairs, for directing our reactions and actions, attitudes and personal indulgences.

Emotions are powerful influences for dominating our course in life. Emotionally-directed individuals arc

all too often enervated and debilitated when their expectations are not met.

Self-mastery means that we are aware of our feelings that tend to push us hither and yon but, more importantly, we ascertain by rational contemplation the elements that tend to drive us, and logically assess and contrive that course which will yield us the most benefits with the least expenditure of resources.

Self-mastery is absolutely essential to well-being and long life in a social/economic environment as exploitative as ours. People who hang their emotional well-being on everything "going their way" will be shattered when adversity occurs as it often does in our society.

The surest way to develop self-mastery is the realization that you are in total control of your affairs relative to all that is outside of you. Once you've trained yourself to stop, reflect and chart a course relative to any matter that rears itself, you can then take a philosophical approach to everything that affects you—and you can help your clients develop a similar attitude.

## **6.2 Security of life and its means are essential to health and long life**

Most humans are provident. As provident creatures, we like to know where our next meal is coming from, so to speak. We want to know that our immediate and long-term future is provided for. Unless we're sure, most of us worry and fret, to our great detriment. Worry is an enervating lapse into emotional solutions to our concerns rather than rational ones. Worriers are not only inimical to their welfare but to the well-being of those whom they touch as well.

Long-lived peoples live in a largely unexploited situation where the needs of life are assured by rather easily expended productive efforts. The simple life does not give rise to the concerns that a complex industrial society engenders.

Unless we have a philosophical attitude that encompasses plenitude and scarcity, one that prepares us to cope with the vicissitudes of our society and economy, we'll have many emotional crises that tear us apart.

In dealing with your clients, try to ascertain their social and economic disposition. Most people are beset by economic worries that lay them low. I've witnessed many a businessman turn grey almost overnight from a business that was going awry due to an adverse marketplace.

Try to inspire and motivate your clients to develop a philosophical approach to social and economic problems and, on the other side, make themselves self-sufficient to the extent they can.

## **6.3 Social and environmental compatibility are essential to well-being**

Humans usually adapt to fit in with the social and environmental circumstances that develop them. Thus we see societies all over the world whose members usually have the same outlook and disposition. We go to India, Japan, China, Tibet, Arabia and any number of other countries and we observe a great diversity of peoples and economies. Though poor by our standards, most Asians do live rather secure lives amongst their peers. The average Thailer or other Asian in a tropical/agricultural economy lives reasonably assured of the needs of life. The relationships of individuals in their societies are rather stable at the community level at least. In America, we have a rather unstable society that drives a substantial part of its members to disposition and escapism as a means of coping with or blotting out the reality of the ugly head of economic and social adversity.

In our society we are more likely to be driven by economic concerns than by human consideration. There are so many individuals in our society who will commit inhuman and inhumane acts in behalf of self-aggrandizement that it agitates and aggravates almost our entire social structure.

Societies and economies oriented to serving everyone and their needs are essential to optimum well-being. At the very least, they must not tend to deny their members the rewards or products of their

efforts.

In our society that is so disruptive to individual and family stability, we must make extraordinary efforts to harmonize with the circumstances that befall us.

## **6.4 Community of peers in life pursuits essential to highest well-being**

"Man is not an island unto himself" has been sagely observed. This is in accord with our gregarious disposition. Humans, need other humans for their best welfare. Alone we wither. There is little motivation in life where meeting our own needs are concerned. As gregarious creatures we are mutually concerned about the welfare of others on a natural level. Within aggressive societies such as ours, our natural disposition becomes vitiated and perverted.

For our highest well-being we should all seek those of similar interests and disposition. It is especially comforting to live among those of similar intellectual and economic interests. We see religious societies wherein its members are stable and self-assured. We see intellectual circles in which members find mutual reassurance and satiation of drives and interests.

The world's longest lived peoples live on their own land for the most part and are subsistence gardeners/farmers/orchardists. Their interests are heavily weighted, to agrarian societies.

We should, for our best well-being, situate ourselves within the context of others of similar interests and pursuits.

[Home](#) > [Lesson 28 - The Elixir Of Life: An Exploration Of Food Conditions, Body Conditions, And Eating Conditions That Beget Euphoric Health And Long Life](#) > 7. Happiness, Enjoyment And Pleasure As Factors In Realizing Life Potential

## **7. Happiness, Enjoyment And Pleasure As Factors In Realizing Life Potential**

These terms characterize our disposition. They are not concrete terms but describe a quality of our being.

These life qualities arise from the overall situation of life. Euphoria is produced by "all systems being in harmony," physical, mental, emotional and otherwise. To achieve these qualities, our life needs must be adequately met in all spheres. We must be free of disturbing factors in all aspects of our being.

A happy disposition is normal and natural to humans. Its absence is an attest to errant disposition or factors that impinge upon it.

### **7.1 The life-sapping effects of depression and despair**

Disenchantment with the prospects of life is occasioned by factors that undermine our well-being. Chronic toxicosis causes suffering that destroys our happiness and that of others as well. Chronic body toxicity vitiates the body and creates a negative life disposition. A sick body makes a miserable member of society that depresses not only the individual but those who become involved with or touch that individual. Just as a smile is a most infectious agent, a miserable individual can cast gloom upon those around.

Suffering makes individuals miserable and misery loves company, even if it has to create it.

Many of your clients will be suffering from the throes of disease. One of the most salutary services you can perform for them is to persuade them to change environments for one to two months to go through a lengthy fast, rebuild some semblance of health and undergo an attitudinal change that makes happiness

and enjoyment virtues after all.

Many people harbor the attitude that virtues of life are strengthened by the adversities we suffer. Many feel that pleasures and joys are inherently sinful or unimportant in the scheme of things. They thus make themselves miserable and attempt to impose their outlook upon others.

You'll meet a multitude of types in your professional sojourn. Vitiating people travel some rather strange paths. Giving their lives new pathways to tread calls for consummate insight and skill. Our endeavor in these lessons is to teach you about everything that bears upon human well-being.

### **7.3 The life-enhancing influences of happiness**

If a smile is the most contagious thing around, then happiness radiates itself like the sun on a clear day. If misery is born of a diseased condition having its basis in toxicosis, happiness is born of a vital body condition having its basis in physiological adequacy.

Thus you'll endeavor to turn your suffering clients' lives around so as to first establish the physiological bases for well-being and then, as much as possible, reach the ideal in life conditions.

### **7.4 The happiness that accrues from a well-rounded life regime**

When all is well in all aspects of our being, only euphoria can result. Thus when we systematically change the practices of a client from pathological to healthful, there will be a more or less complete reversal of the client's feelings and disposition. Of course you'll find that there are some psychologically and physiologically handicapped individuals beyond total redemption, but even so, you'll probably find many areas in which improvement is possible, meaning restoring more happiness to a lost life.

Life is meaningful when we enjoy it. As a Life Science professional, you will be instrumental in helping people to make themselves happy.

[Home](#) > [Lesson 28 - The Elixir Of Life: An Exploration Of Food Conditions, Body Conditions, And Eating Conditions That Beget Euphoric Health And Long Life](#) > 8. Questions & Answers

## **8. Questions & Answers**

**There is no proof that a raw food diet of fruits and certain vegetables, seeds and nuts, in correct combination, without herbs and spices, promotes health and longevity. Show me a group of people over the age of 100 who have been living according to your principles.**

In situations like these you can put the onus of the negative on the questioner. You can haul out such statistics as presented in *The Myth of Health In America* and show that these problems are caused by cooked foods, condiments, wrong foods, etc. Better yet, ask the questioner why this should be so. You can point out Kouchakoff's experiments that show cooked foods to be pathological because they cause leukocytosis.

But, of course, you can get books about the Hunza and Abkhasia. These are mostly raw food eating people, especially the Hunzas living where they have no fuel to speak of. Hunzas are a healthy long-lived people with a great percentage of their population over 100 years of age. Their primary fare consists of apricots, apples, mulberries, peaches, grapes and other fruits

other problems is an example of the error of living. There is no defense for dietary and other perversions for a person who is suffering because of those very perversions.

Depriving yourself of junk foods and nonfoods is like depriving yourself of hell. What do we seek, hell or heaven? We make our own.

**People have been using garlic and onions for thousands of years. They have hastened healing with them. If, when seriously ill, garlic is given and the patient recovers, why then does not the disease return when the patient recovers?**

Yes, people have been eating garlic and onions for thousands of years. People have been sick and diseased for thousands of years and continue to be so despite all the garlic and onions eaten. You can demonstrate to yourself that the primary "medicinal" factors of garlic are mustard oil and allicin. These substances are indigestible. They readily permeate tissues and cells. They are excreted through the lungs and kidneys as the same substances that enter the body—as mustard oil and allicin. If they were digested and used, those who eat these obnoxious lily family members would not stink to high heaven. If you crush a clove of garlic in your hand and hold it a few minutes you'll have garlic breath within ten to fifteen minutes, demonstrating the permeability of cells and tissues by these pernicious substances. Use and control of anything that gets into the body which it cannot digest, is difficult.

We don't need penicillin or bactericides in our bodies. Killing off our symbiotic bacterial flora is harmful, not helpful. TB is a disease wherein the body dumps its toxic materials into the lungs in the same way that asthmatics have their extraordinary toxicity exuded through the bronchioles or the sinus sufferer excretes toxins through the sinuses. Garlic has no intelligence at all and could not heal TB under any circumstances inasmuch as TB is a body-instituted measure to cope with body toxicity. Garlic will so drug the body as to reduce, its vitality and increase its accommodation to both the garlic and the toxicity. But we're less healthy for that, not more healthy. It is a fabrication to say the body will be free of disease if its causes are still indulged.

Fasting enables the body to speedily eject its toxic load whereas drugs, including garlic's allicin and mustard oil, tend to suppress elimination.

**Why are dairy products bad when almost everyone who is long-lived uses them?**

This is not true, of course. The Hunzas do not use milk except for children and this is from mother's breasts. The Vilcabambians do not use dairy products. Among the world's longest-lived peoples, only the Eastern Europeans use dairy products. And to attribute their long life to these products is like attributing their long life to the wine and tobacco many of them also use. The fact is they have long life not because of these things but despite them. It's what they're doing right, not what they're doing wrong, that keeps them alive so long. Undoubtedly they'd live much healthier and longer if they did everything right.

We have humans living to be in excess of 100 years on fruits alone. We have Orangutans living to be 125 to 150 years on fruits alone. Is not this an argument for eating fruits alone? Regaining health while on goat's milk means, if we study such cases, that all those dietary practices which contributed to previous pathology were dropped—causes were discontinued. Suckling goats is not as healthy as eating fruits. Shouldn't we take two groups of individuals as controls, put one on a mono diet of goat's milk and the Mother on a diet of fruits and see how they fare? Because most humans lose the ability to secrete lactase, the enzyme that breaks down lactose, and because almost all lose the ability to secrete rennin, the enzyme that breaks

down casein, we cannot thrive on milk. Please note that those long-lived peoples did not use fresh milk but fermented milks. Those who take fresh milks, raw or pasteurized, suffer much disease.

Dairy products are not wholesome. America consumes more milk and milk products than all the rest of the world combined. By all standards we should be the healthiest but, on the contrary, we're the most diseased, as statistics attest.

**How can grains, especially breads and cereals, be bad, when almost all the centenarians use them in one way or another?**

This is not true. The Vilcabambians eat only corn of all the grains and little of this—their primary foods are fruits and potatoes. The Hunzas eat very little grain because they have little room for growing grain. Fruit trees are the most productive of food and the Hunzas eat a preponderance of fruit.

A characteristic of all centenarians is that they are not gluttonous eaters of anything—they eat abstemiously.

Americans are among the biggest grain and meat eaters in the world. Why aren't we or the Canadians or Australians or other grain-eating countries noted for longevity? The Chinese and Japanese live heavily on rice but their longevity hardly exceeds ours. What are the supposed virtues of grain? It must be eaten cooked and largely devitalized. It furnishes calories and most of its products are deficient unless eaten with lots of raw greens and vegetables.

The Finns are a vigorous but not a long-lived people. They are heavy fat and grain eaters and have disease conditions rivaling our own country. More Finns die of heart attacks than do Americans. Whoever holds up the Finns as examples of healthy long-lived peoples is awry in the belfry.

**What possible reason can you give for advocating water fasts as opposed to juice fasting?**

Fasting involves a diet of only water, whereas a better term for juice fasting might be "juice feasting."

In the water diet, the body shuts down the digestive tract and devotes its energies to bodily rehabilitation. On the juice diet, it must continue to carry on digestive and eliminative functions in the intestinal tract.

Under a complete fast, beneficial results are obtained quicker by a ratio of three to five to one over that of juice dieting. Further, cleansing and healing can be accomplished on the water diet that cannot be accomplished at all on a juice diet.

Juices are fragmented and incomplete foods and fail to furnish many of the needed nutrients that are bountiful in the whole foods. Further, juices exposed to oxygen rapidly oxidize with the result that their nutrients are lost. Moreover, those oxidized nutrients are transformed into toxic products, especially the minerals which are often largely returned to an inorganic state.

The body greatly improves on a simple diet but, I repeat, improvement is much quicker and more profound on a water diet with benefits being realized that may not be realized at all on a juice diet.

A juice diet for 20 to 40 days is of immense benefit but 10 to 12 days on a water diet will

yield even greater benefits. The lies about fasting are many and the supposed advantages of juice dieting are nonexistent. Because of their oxidized and deficient nature, the juice dieter may suffer drug effects which are often confused with beneficial effects.

When we modify our diets or fast, we seek maximum benefits and water dieting is superior to everything else. After a few days on the water diet, hunger goes away and we have no urge to eat. On the juice diet, there are periods of intense hunger and periods when hunger is absent. If juices are not taken when hunger is absent and water taken instead, the fast is great. But if foods are taken when hunger disappears, even be it juices, the purposes of the body are thwarted.

### **How can you say that too much starch and protein is bad when the Irish people use them in large amounts and suffer no ill effects?**

The Irish live mostly on potatoes with some fish. They are not gluttons as are Americans and they conservatively cook their foods. They are not noted for their longevity and few centenarians are among them. In fact, their health is hardly better than our own. They are vigorous outdoor people. Most heavy laborers are. But how many athletes are really healthy people in this country? Athletes die young like most other Americans because they partake of about the same diet as most Americans.

In reading the book you submitted, it would appear almost everyone in the world is healthy but we Americans. The truth is that most of the world is unhealthy except for little pockets of people here and there who enjoy relatively better health.

There are a multitude of factors that contribute to health and food is only one. While food can undermine health no matter how good other practices are, it cannot assure health no matter how perfect if all other practices are bad.

Starch must be cooked to be eaten. We cannot handle raw starch except in small quantities. Cooking dextrinizes starches. All starches must be converted to simple glucose and fructose before it can be absorbed. This is done at great expense to the body. Why not take fruits that are glucose and fructose to begin with? There are no good arguments for starch-eating.

What goes for starches goes three-fold for proteins. While there are proteins in every food, most human protein eaters cook and degenerate the protein content anyway. The proteins are coagulated and the amino acids deaminized. The body is only about 30% efficient in using protein as energy whereas it is about 90 to 95% efficient in converting fruits. And as far as the protein needs of the body go, about 70% can be secured from recycling our own metabolic wastes whereas actual needs are met amply from fruits. Proteins in excess of our needs putrefy in the digestive tract and, if absorbed as amino acids and are excessive, the body must tax itself greatly in decomposing them and ridding itself of the toxic by-products.

Those who insist on their perversions to the point of being hopeless are choosing a life of suffering.

### **If mineral waters are harmful, the Hunzas would have been dead a long time ago.**

This, of course, is the most idiotic of all conclusions. First, inorganic minerals cannot be used by the body. Iodine and many other minerals are absolutely essential in human nutrition but, in inorganic form, are rank poisons. The body can use them only in organic context.

The Hunzas are not great water drinkers, their diet being mostly water sufficient. Secondly,

their water starts out as pure a short distance from their uptake of it and it is full mostly of sediment, not minerals in solution. They settle out the sediment just as any sane person would—who wants to drink sand and minute rock debris? Who wants to drink soil? During the brief run down the mountains, the water picks up lots of sediment but few minerals in solution. And, to top it off, Hunzans drink very little water anyway. Certainly, raw materials and rock are not healthful.

Human mineral needs are only about 8 grams daily by the doubled and tripled standards of RDAs. Yet a normal diet of raw foods furnish intact about 20 to 25 grams of organic minerals daily which the body can use.

Be it noted that the fabulous waters the Hunzas get from their glacial runoff is available only for a few hours a day during the warm months, being totally unavailable most of the year.

### **Why are herbs so harmful? If so, how did Li Chung Yun live to be 256 years old?**

If Gotu-kola and Ginseng teas were the only vice of this long-lived sage, then we should not marvel at his longevity. Little is said about his diet except that it was vegetarian. Does it not sound reasonable to attribute health and longevity to healthful living instead of to wines, cigarettes, fermented and rotted products, teas, toxic botanicals (both these herbs are listed in books on botanical medicines as possessing toxic substances).

Those who continue to indulge in their vices under the purblind rationalization that long-lived peoples had this or that vice usually end up with heart conditions and/or cancer which do them in at an early age. Rationalizing our vices and perversions will not deliver health.

### **Why do Bulgarians live so long when they do everything you advise against?**

This question embodies a falsehood. They do not do everything I advise against. On the contrary, their lives are far more healthful than that of the average American. Your documentation of what they're doing wrong indicates they're doing mostly right. Only about 3 to 4% even partake of meat at all. Most live on fresh fruits and vegetables according to the published material you sent. Especially stressed was their consumption of sunflower seeds. Bulgarians do partake of fermented milks but it is not by any means the predominant part of their diet. Their hard work in the out of doors and their relatively stress-free society are not debilitating but, on the contrary, very healthful.

Beware of people and writers who want to credit health and longevity to the oddball perversions people may have rather than to their preponderance of healthful living practices which are the only basis for health and longevity.

## Lesson 29 - Why Condiments Should Not Be Included In The Diet

[Home](#) > [Lesson 29 - Why Condiments Should Not Be Included In The Diet](#) > 1. Condiments, Seasonings and Spices

### 1. Condiments, Seasonings and Spices

The ancient Egyptian mummies are masterpieces of the embalmer's art. For thousands of years, the bodies of kings and queens have been preserved by an intricate process that was once a closely guarded secret of the priests. Exotic substances, "magical" potions and hard-to-find agents were used to tighten the flesh around the corpses of royalty and preserve them from decay over the centuries.

Today we know what those exotic ingredients are that caused the flesh to petrify. In fact, you probably eat those same preservative substances each time you eat in a restaurant, prepare cooked foods or buy processed foods. Salt, vinegar, oils, spices and various herbs—all found in most American kitchens—were originally used by the Egyptians to embalm their corpses. Only now, we are using the same items to preserve, petrify and embalm the bodies of the living.

Making mummified corpses was the original use of seasonings that modern man now sprinkles so liberally over his food. What effects do these spices have on the living organism and how did their use begin?

#### 1.1 The Original Use of Spices

Spices, salt and seasonings were first used to preserve food and to disguise the taste of food that had gone bad. Rotting meat and old vegetables that had been heavily spiced could be eaten without disgust. Salted food could be carried for weeks without decay.

The use of spices became prevalent in Indian and Chinese food at about the same time these countries elevated cooking to a "fine art." The European countries later adopted the spice habit of the Eastern countries as they began to process and cook more and more of their foods.

These items used in cooking are known as condiments and they seem to have had their start at about the same time man abandoned his diet of primary fresh and seasonal foods and started to use more and more meats, cooked and processed foods.

## 1.2 What Is A Condiment?

A condiment is generally something "extra" that is added to a food for "flavor" or taste stimulation or even for its preservative properties (like salt and vinegar). In other words, condiments are used for the taste "satisfaction" that it might provide and not for any nutritional value.

Is a condiment also a food? Generally not. A substance that is eaten is either a natural part of the human dietary or it is a nonfood item that is used for some reasons other than nutritive ones. Condiments have little or no nutritional value.

A true food may be eaten in such quantities that it can be a complete meal by itself. You can eat all you desire of a natural food, to repletion and satisfaction, and suffer no harmful effects. Of course, you can overeat any food, natural or otherwise, but generally speaking, you can certainly eat several mouthfuls of a natural food quite safely.

There is no way that you can eat several mouthfuls of salt, cinnamon, vinegar, black pepper, cayenne or mustard. In fact, a few bites of most condiments can prove fatal.

If condiments must be used in such small and careful amounts, how can they be considered foods for the body? The fact that we can eat a small amount of salt or pepper, and not drop dead, does not mean that these foods are any less poisonous. Instead, we're taking nonlethal doses of these condiments. Just the same, they still exert a disruptive effect on the well-being of the body no matter what the quantity eaten. A poison is a poison, and a little will kill us just as surely, (although more slowly) than a lot.

If you are ever in doubt if a substance is a suitable food or a condiment to be avoided, simply ask yourself this question: Could I eat a mouthful of this enjoyably? If not, it should be avoided.

## 1.3 The True Nature of Condiments

The greatest living proponent of Natural Hygiene, Dr. Herbert M. Shelton, described the true nature of condiments and food seasonings in his book *Human Life: Its Philosophy and Laws* in the following manner:

"Among the unwholesome substances demanded by perverted taste are the condiments and 'relishes.' These things possess little or no food value and there does not exist a single excuse for their use.

"They blunt and deprave the sense of taste, so that the natural flavors of foods are neither detected nor appreciated. They overstimulate and weaken the glands of the mouth, stomach and intestine. They irritate the lining membranes of the alimentary canal, causing these to thicken, toughen and harden, and they impair their functional powers. They create a fictitious desire for food and induce overeating. They create a false thirst, one that cannot be satisfied with water. They retard and derange digestion.

"They disguise the food eaten. When the food is camouflaged by salt, pepper, mustard, vinegar, nutmeg, spices and other condiments, the digestive juices are not appropriately adapted to the food eaten. Digestion suffers as a consequence.

"No one need ever develop a craving for these substances and where it is already developed, it can be easily overcome if one will give up their use and persist in abstaining from them for a time. When the sense of taste is restored to normal, you will find fine, delicate flavors in foods that you never knew existed."

## 1.4 Condiments Are Everywhere

If you eat in a restaurant, use any processed foods or shop in a supermarket, you're going to be exposed to condiments. There are hundreds of flavor enhancers, spices and seasonings added to almost all of our foods. To avoid them, you'll have to prepare your own food from fresh ingredients.

Why do we use so many condiments?

When foods are processed or cooked, most of their natural flavors are lost. This is the reason that foods which are cooking smell so strongly—all the flavors are being cooked out of them into the air. The food that remains behind is flavorless and flat. Salt, spices and seasonings are used to re-add "flavor" to the food that was cooked away. The condiments substitute for the natural flavors present in wholesome foods.

Some foods such as meat and grains often have so few appealing natural flavors to begin with that condiments are used to make them "more palatable." This should be an indication that these foods are not suitable for the human dietary.

Fresh, raw fruits and vegetables are full of subtle flavors and aromas. When eaten in their unprocessed state, these foods provide a full range of taste and olfactory stimulation without the need for artificial and added flavorings.

Since there are so many condiments in use today, only the major ones will be discussed. A listing of other widely used condiments will also be given according to their classification so that the student may learn to recognize the wide range of condiments that exist.

[Home](#) > [Lesson 29 - Why Condiments Should Not Be Included In The Diet](#) > 2. Specific Condiments

## **2. Specific Condiments**

### **2.1 Salt**

Salt is the most widely used condiment in the world. Last year Americans ate over 275,000 tons of table salt, and on the average each person in this country consumes five times as much salt as any other world citizen.

Many men, women and children in this country eat an average of 10 to 12 grams (almost one-half ounce) of salt every day. America also has over 25 million people suffering from hypertension or high blood pressure, the third major cause of death in this country.

There is a connection.

Table salt is an inorganic mineral compound composed of sodium and chlorine. It has antibiotic and preservative properties. Although not generally thought of as a poison, salt is deadly to all living organisms. A fatal dose of salt is usually about four ounces taken at one time. This is only eight times more than the average person eats over a day's time.

Salt is probably the most ubiquitous seasoning in the world. You'll find it in almost every processed, prepared or preserved food. We even put it in our pet food and baby food. Even if no extra salt is added at the table, the average American diet will still contain over six times what most nutritionists consider "safe" levels of salt usage.

There is no safe level of salt use.

#### **2.1.1 The Myths of Salt**

If salt is so bad, why do we use it. all? Is there really a need for salt in the diet?

Salt use has been defended on these four misconceptions:

1. Salt is necessary for life.

2. Salt improves the flavor of food.
3. Salt promotes digestion.
4. Salt is found in the bloodstream and must be an essential ingredient of the living organism.

Let's look at each one of these beliefs and see if they are based upon any truth.

### **2.1.2 You Don't Need Salt To live**

The most common defense for salt is that the body has certain sodium and chlorine mineral needs that the sodium chloride (table salt) crystals are thought to fulfill. Sodium is used by the body to maintain a water balance, to integrate nervous functioning and to aid in the formation of digestive juices. Chlorine helps sustain normal heart activity, plays an important role in the body's acid-alkaline balance and aids digestion and elimination.

Salt (sodium chloride) cannot be used by the body to meet any of these mineral requirements. Salt is an inorganic mineral that cannot be metabolized by the body. Salt enters the body as sodium chloride, it circulates in the body as sodium chloride, and it leaves the body as sodium chloride. At no point is it broken down into sodium and chlorine and used by the body.

Sodium chloride is a very strong and stable molecule. It cannot be broken down in the digestive tract or by the liver. The body cannot use the bonded sodium chloride molecule in any way. The body can use organic sodium and organic chlorine as found in living food (vegetables, fruits, etc.), but it can never use the inorganic sodium chloride compound.

So, if the body cannot break salt down, if it cannot use it in any way, if it only must be eliminated from the body in the same form as which it entered the body, then how can salt be termed "necessary" for life?

Moreover, salt eating has only been around for the last few thousand years of man's millions of years of existence. Primitive man did not eat salt. The American Indians never used salt until the white man introduced it. Many cultures today have never seen a salt shaker. Thousands of Hygienists and health-minded people in this country eat not one speck of salt.

Can you still believe that salt is essential for life?

### **2.1.3 Does Salt Make Food Taste Better?**

Even if people are convinced that salt is of no nutritional use, they will still defend it as a flavor enhancer. "Salt makes my food taste so much better," is the common justification for salt eating. But can salt add flavor to your food?

Taste a pinch of salt. What flavor does it have? Is it appetizing and does it have a nice taste? No. Then how can it add flavor to food if it has no flavor of its own?

Salt performs its "flavoring" by actually irritating the taste buds on your tongue. By inflaming the tongue, salt makes the taste buds more sensitive through chemical irritation.

It's like burning all the skin off your hands so you'll have more sensitive fingers. Ever notice how a sore and inflamed spot on the skin is more sensitive than surrounding areas? Salt does the same thing to your taste buds—it makes them sore and sensitive. Consequently, you notice taste stimulation more, but you're not experiencing the actual flavor of food in any greater amount.

Salt can't add flavor or anything else to your food. It's a chemical. A chemical can't give you or your food anything extra, except perhaps some irritating stimulation that is mistakenly identified as "flavor."

### **2.1.4 Does Salt Help Digestion?**

Salt has been defended as an important aid in food digestion.

Consider this: your body alone digests food. The enzymes and gastric juices produced by the body

interact chemically with the food you eat as one of the stages of digestion. Sprinkle some salt on a tomato slice. Does the salt digest the tomato? Does it do anything! No. Salt is an inert substance—it is a nonliving, inactive mineral. How can an inorganic crystal enter into such an organic process as digestion?

Even traditional nutrition no longer believes that salt by itself is a digestive aid, but they do state (as recently as 1980) that the chloride ion in salt helps form the hydrochloric acid in the stomach which is used to digest food.

This, too, is faulty reasoning. The chlorine in salt cannot be metabolized by the body in any way. It does not enter into any body process. It remains bonded to the sodium atom. Now organic chlorine as found in living foods can be incorporated in the production of hydrochloric acid, and thus "improve" digestion. The chlorine in salt, however, is inorganic and cannot help the digestive function in any way.

Instead, here is what happens during the digestive process when salt is eaten:

1. the absorption of food through the intestinal membranes is inhibited;
2. protein solubility increases and a considerable loss of tissue building material occurs in the urine (a pathological condition known as "albuminuria");
3. the water balance in food digestion is disturbed, thus slowing digestion.

In short, salt does not enhance digestion; its presence in the body actually retards digestion.

In Japan where salted and pickled foods are a dietary mainstay, the incidence of stomach cancer is higher than any other place else in the world. There is a definite link between high salt use and stomach cancer.

Does a cancerous stomach sound like digestion is being improved?

### **2.1.5 Is Salt An Essential Part of the Blood?**

Since salt is found in the blood, people think that we must consume it for healthy blood. There are "salts" in the blood, and sodium chloride is among these other mineral salts. But does this prove that table salt is an essential ingredient of the bloodstream?

Most people have eaten so much salt all their lives that there is a continual circulation of sodium chloride through the bloodstream. The reason that the salt is in the blood is that the body is constantly trying to eliminate it from the system.

A typical salt-eater has so much salt in the body that the body can never catch up on its elimination. We are probably capable of excreting around 200 milligrams of salt a day through the kidneys (this is about as much salt as can be placed on the end of a sharp-pointed knife). Most people eat fifty times that much. So where does all this extra salt go? It's stored in layers beneath the skin to be eliminated by perspiration, and it is also continually circulating in the bloodstream, waiting to be processed by the overworked kidneys.

Of course there is salt in the bloodstream. There are also pesticide compounds, drug poisons and environmental toxins as well. Does this mean (hat these are also an essential part of the blood? The bloodstream circulates wastes and poisons for elimination if we put them into the body. Salt is just another one of these toxins that we have introduced into the body.

Organic mineral salts are also in the bloodstream, and these are used by the body for a number of functions. Inorganic table salt, however, is only a poison that the body must try to eliminate.

### **2.1.6 And Take This With a Grain of Salt...**

Amazingly enough, many nutritionists today still recommend that everyone consume a minimum daily requirement (MDR) of salt. The most frequently estimated MDR for salt is 200 milligrams. Most

Americans consume fifty to seventy-five times that much every day. In fact, no national diet anywhere in the world contains less than this MDR for salt.

Consider this: if salt cannot be used by the body, if it is poisonous, if it is implicated in a wide variety of diseases and disorders, then why should we consume a "minimum required amount" each day? Not only that, but conventional nutritionists also state that an infant's salt needs are relatively greater than an adult's needs! Does anyone need a poisonous substance, especially a child, in no matter how small an amount?

For an even more surprising twist of logic, consider the actions by the Senate Select Committee on Nutrition and Human Needs regarding salt use by the American public.

In 1977, this committee recommended that salt consumption be reduced to 3 grams a day (still 15 times more than official MDR levels). In response, a task force of 14 scientists representing various food processing industries issued a statement that read in part "only 3 grams of salt per day would provide an unpalatable therapeutic-type diet that would require exceedingly careful selection of foods from a limited list." After this statement, the Senate committee decided to revise its official recommendation to 3 grams per day.

Still later, upon inquiry from the president of the Salt Institute, the committee stated that the 5 grams recommendation was for additional salting that might be used above the already 3 grams of salt present in a typical American diet. So now the recommendation for total daily salt intake stands at 8 grams per day (or about 1/3 ounce).

Perhaps you can see how such figures as "MDRs" and "government recommendations" should be taken with a "grain of salt."

The important thing to remember is that if you would eliminate all inorganic table salt from your diet and consume "0" grams a day, you would experience a higher level of health and add years to your life.

### **2.1.7 Salt Is Antibiotic**

Salt was originally used as the first food preservative. It was discovered that when meats and vegetables were salted, decay was decreased.

Food often spoils depending on its "water activity" level. Food can either be dried to reduce its water activity or it can be salted. Salt affects the water activity in food so that bacterial growth is prevented. In other words, salt is an antibiotic.

Antibiotic means literally "anti-life." Salt is precisely that; it destroys bacteria and it will destroy the living cells in your body as well.

If you cannot always have fresh foods, there are better ways to preserve food than salting. Drying food or storing it at low temperatures is the best way to prevent bacterial growth. There is absolutely no reason to add salt to food preserved in other ways, such as canned or frozen foods, since this is only done for "flavoring."

### **2.1.8 Final Thoughts about Salt**

Hypertension (high-blood pressure) is one of the most common illnesses today. It accompanies coronary heart disease, stroke, congestive heart failure and kidney disease.

A 35-year-old man with blood pressure 14% above normal has lost 9 years of his life expectancy. A 45-year-old man whose pressure is 17% above normal runs twice the risk of a heart attack and four times the risk of a stroke as a healthy individual.

When the diet consists of 2.8% salt, as is typical of Americans, it is described as "frankly hypertensogenic and life-shortening."

Salt is a strong diuretic and causes water to be used from the blood and lymph to excrete it through the kidneys. This is why salt makes us thirsty—the body demands more water in order to flush an irritating substance from its tissues.

The continued use of salt causes a severe affliction of the kidneys called "nephritis."

Salt causes inflammatory swelling of the glands.

It contributes to constipation and indigestion.

It is a factor in many skin diseases.

It is deposited throughout all the fluids of the body, which causes extreme irritation, injury and death to billions of cells.

It is toxic. It is poisonous. It cannot be used by the body in any amount.

*Don't limit your salt use—eliminate its use.*

## **2.2 Cayenne Pepper**

Hot peppers are often used to spice up dishes, especially in Mexican, Oriental and Indian cooking. Cayenne or red pepper is perhaps the most popular, and it is also often recommended by herb enthusiasts as a general "cure-all."

Jethro Kloss, an herbalist and author of *Back To Eden*, described cayenne pepper as "one of the most wonderful herb medicines we have...it is good in all forms of diseases, and is almost a certain remedy for all maladies." He and other herbalists have advised us to gargle with cayenne pepper, put it on open wounds, use it for ulcers and to sprinkle it in our socks to keep our feet warm. There has been a lot of promotion for cayenne pepper and many people have been convinced that it can be used for all manner of ailments.

The truth is that cayenne pepper, along with all other hot peppers, chilies, etc., contain harmful alkaloids which are even more injurious than the common black pepper. When cayenne and hot peppers are eaten, the body is thrown into an emergency state in an attempt to eliminate the toxic oils and substances in the peppers.

Suppose a young child eats a hot pepper, what happens? Most likely, he will cry, he may vomit or experience diarrhea, and he will certainly feel like his mouth and stomach are on fire. He will not be anxious to repeat the experience. A child's body is still pure and sensitive enough to detect the harmful substances in hot peppers. An adult who has abused his digestive system for a number of years on a conventional diet merely experiences that momentary burning warning which is the weakened body's signal to avoid the hot pepper.

All hot peppers contain a poisonous alkaloid called piperidin and a harmful crystalline substance known as piperin. Hot peppers also have acrid resins and volatile oils which irritate the digestive and urinary tracts. Cayenne pepper also contains an alkaloid called capsaicin which irritates the body so severely that circulation is rapidly increased in order to remove it from the system.

This is why hot peppers make you feel "warm"—the body drastically increases circulation to remove all the harmful pepper alkaloids as expeditiously as possible.

Cayenne has probably achieved its reputation as a "beneficial" condiment for two-reasons: it is initially painful (burning) to eat, and it causes a mucus outflow from the body.

Since hot peppers are burning, irritating, and only able to be eaten in small quantities, we think that they must be a "powerful" medicine. In other words, if it burns so much, it must be doing us some good, right? Since all nonfood and medicinal substances are distasteful, the strong taste of cayenne is associated with a medicinal action. It's strong and it burns going down, so it must make us tough and strong if we can eat it—or so the reasoning goes. The idea of "strong" medicine and "powerful" foods is

a carryover from the primitive beliefs in magic and superstition, but it still remains with us today.

Second, because there is a mucous outflow when cayenne is eaten, people often think that the pepper is cleaning out old mucus deposits from the body. Instead what is actually happening is that the cayenne is such a powerful irritant, *the body secretes extra mucus in order to eliminate the harmful alkaloids*. Cayenne only causes additional mucus to be produced as a defensive measure by the body. This extra mucus coats the harmful substances in the peppers in order to protect delicate body tissues. Foods don't eliminate mucus from the body; the body eliminates mucus from the body.

Since the body is stimulated into emergency action by the cayenne, people mistake this stimulation for proof that the pepper is making them "strong." The body feels more vital after eating the pepper, and this is because the system must go into an unnatural overdrive in order to eliminate the foreign substance. Eating cayenne pepper for "strength" makes the same sense as beating a dying horse to make it move faster. Motion increases to escape the inflicted punishment, but death is only hastened.

Cayenne pepper and other "hot" foods cannot impart any additional healing powers to the body. The body alone can heal itself, and stimulating it with poisonous alkaloids hardly seems wise.

Cayenne pepper is an irritant, and any stimulating effects it may produce are done so at the expense of the body's well-being.

## **2.3 Cooking Spices**

There are many different cooking spices, such as nutmeg, cinnamon, allspice, ginger, cloves, mace, and so on. All of these spices contain harmful volatile oils and acrid resins which irritate the digestive tract. The net effect of using these spices in foods is that the body tries to hurry the irritating spices through the gastrointestinal tract to minimize the harmful effects.

This is why spices are thought to help the digestion of food—in reality the food, instead of being properly digested, is simply speeded toward the nearest exit for rapid elimination. Spices are stimulants and irritants and their presence in food negates most of the nutritional value of the food eaten.

## **2.4 Cinnamon**

Cinnamon is the bark of the cinnamon tree which is powdered and dried. It contains one to two percent volatile oils and a considerable amount of *tannin* which gives it the bitter aftertaste. Tannin is an astringent that is also found in common tea. It is toxic to the human system.

## **2.5 Nutmeg**

Nutmeg is the powdered kernel of the fruit of the nutmeg tree. The outer covering of the kernel is used to make the nutmeg spice, while the inner coat is used to make the spice called mace.

Nutmeg is fatal in large doses, leading to convulsive seizures. Large nonlethal doses produce prolonged hallucinations similar to psychedelic drugs.

## **2.6 Mustard**

Mustard is made from the seed of the mustard plant. Besides the harmful vinegar, salt and other condiments in table mustard, the seed itself contains certain alliaceous oils like the garlic and onion plants. These oils are very irritating to all tissues of the body and produce a disagreeable odor.

Horseradish has the same undesirable oils and properties as mustard.

## 2.7 Vinegar

Vinegar is the result of acetic fermentation of alcoholic liquids. Vinegar is very injurious to the digestive organs, and it does not matter if it is white vinegar, cider vinegar, or whatever its source.

Vinegar reduces the number of red blood cells, greatly retards digestion and assimilation, and harms the kidneys. When used in conjunction with starchy foods, digestion is completely suspended and fermentation rapidly results.

## 2.8 Other Condiments

There are numerous other condiments, and some of them, such as garlic, onion, herbs, etc., are discussed in detail in other lessons. To help you identify various condiments, the following table and categories may prove useful.

[Home](#) > [Lesson 29 - Why Condiments Should Not Be Included In The Diet](#) > 3. Condiments In General

## 3. Condiments In General

### 3.1 The Classification of Condiments

Class	Examples
Aromatic	vanilla, cinnamon, clove, parsley, bayleaf, rosemary, caraway seeds, cumin seeds and most herbs.
Acrid or Peppery	black and white pepper, cayenne, chilies, curry, allspice, ginger.
Allylic or Alliaceous	garlic, onion, mustard, horseradish, chives, leeks.
Acid	vinegar (white, cider or wine), capers, gherkins.
Animal	caviar, anchovies, beef boullion.
Mineral	salt (earth, sea, or chemical), and all salt-based seasonings (miso, soy, tamari, etc.)

There are many other food items that are also used as condiments by themselves, such as relishes, mayonnaise, pickles, chutneys, spreads, dips, etc. All of these contain a high percentage of the above-listed condiments and should be strictly avoided by any person desiring good health.

### 3.2 The Best Condiment

*The best seasoning is a hearty appetite.*

## 4. Question & Answers

### Can you name any safe salt substitutes?

If I were hitting you in the head with a hammer, would you ask me to stop or to use a softer hammer? Seriously, you don't need a substitute for a poisonous substance. By using such items as potassium chloride salt, kelp, herb seasonings, and other substitutes, you're still keeping the salt-shaker habit alive, and you'll never be able to develop an appreciation for the natural flavors of wholesome foods. When you eat fresh foods in a mostly raw state, you'll have absolutely no desire for salt or for any "substitute." Now, I'll give you a second answer. Yes, there are some alternatives to salt and seasonings that you can use as you are becoming established on a fresh food diet. Freshly squeezed lemon juice stimulates the taste buds like salt, but without the irritating and harmful effects. A little lemon juice over nonstarchy foods is a permissible alternative to salting until your taste buds come back alive.

You might also consider eating those fruits and vegetables that are high in organic sodium and mineral salts. Celery, beets, carrots, cabbage and dried figs are high in organic mineral salts, particularly sodium, and may help you away from the salt habit. A salad with chopped celery and lemon juice, for example, creates a very salty taste.

After you have been off salt for a few weeks, you won't miss it all. If you start using "substitutes," however, you're still perpetuating the seasoning habit and it may make it more difficult for you in the long run.

### What about black pepper? You didn't discuss this in the lesson.

Black pepper is not an actual pepper, but is made from the dried berries of a tropical shrub. Whereas hot peppers like cayenne and chilies are primarily stimulants, black pepper is chiefly an irritant. It has particularly harmful effects on the intestinal tract.

Allegedly, black pepper is 47 times more detrimental to the functioning of the liver than is alcohol. White pepper, often used by gourmets, is simply the ripened berries of the pepper shrub.

### I guess I can see how you would need few if any seasonings on a raw food diet. Fruits are delicious without any salting, etc. But what about raw vegetable salads? These are so boring without some kind of interesting dressing.

A raw vegetable salad can be made very flavorful and enjoyable without any condiments. The secret? Eat your salad whole. Don't cut it up into a hundred pieces and then mix it all up. Simply eat each vegetable, like a tomato, broccoli stick, etc., as a separate piece. When you cut, chop and mix your salad, you are losing the individual flavors of each vegetable. By the third bite, the whole salad tastes the same—there is no flavor or texture contrast.

A whole salad, uncut, requires no dressing. Take one bite of one vegetable, then a bite of another, and you can be suitably "entertained" without spicy and oily dressings. You can also eat a few nuts, seeds, or avocado with your salad—also in their whole form if teeth permit-

along with the whole vegetables. Believe me, when you eat a "finger salad"—all whole vegetables—you get more enjoyment and less vitamin loss than if you chop and mix everything up in one big bowl.

Condiments, dressings, etc are usually desired when the original flavors and integrity of a food are lost. Eat your foods whole, and you can appreciate all the wonderful subtle flavors that are there.

**It seems that since we use such small amounts of seasonings that they couldn't be all that harmful, I mean, a little pinch of something couldn't hurt you that much.**

You can only use a "little pinch" because condiments are such potent and strong nonfood items. This should tell you something. Even a very small amount of a condiment will disrupt the natural digestive processes. The human organism is very sensitive to all toxins and poisons. As you refine your diet, you'll begin to notice the undesirable effects of even those "small amounts" that you previously used.

[Home](#) > [Lesson 29 - Why Condiments Should Not Be Included In The Diet](#) > Article #1: Are Any Condiments Acceptable In the Hygienic Diet? By T.C. Fry

### **Article #1: Are Any Condiments Acceptable In the Hygienic Diet? By T.C. Fry**

Very frankly this is an area in which I have not done much research and do not propose any. Why? Because condiments are stimulants (irritants) that cause the taste buds to go into a frenzy—they become "super charged."

The taste buds become so sensitive to the substances being eaten—including the flavors of the condiment or condiments—that we become more intensely aware of the flavors. The simple truth is that we should not be eating food that requires condiments to camouflage, modify or heighten its taste.

Salt is America's favorite condiment. It has no food value. It is not digested. It is eaten merely for its taste—its ability to give the illusion of flavor where the food's innate flavors and mineral complement are largely or wholly missing. Salt is poisonous, though it usually kills its victims slowly.

The catalog of condiments is long. Vinegar, herbs, catsup, aromatic seeds, seasoning, salts, dried peppers, pickles, mustard, sauces, relishes, onions, dressings, garlic, shallots, spices, etc. all fall under the heading of condiments. Some have food value and some don't. But one thing they all have in common is that they all contain poisonous compounds. These compounds irritate not only the taste buds but other body cells and tissues as well.

Dressings are usually loaded with condiments. Basically they have an acid (vinegar as a rule), a fat (oil, mayonnaise, egg or other), sugar or honey, salt and other spices. They are a dietary abomination and render food with which they are combined mostly indigestible despite the "terrific" taste.

As a fruitarian, most of my intake is of fruits and they need absolutely nothing extra. Nothing can make my pears, apples or grapes taste any better—they taste wonderful just as nature delivers them.

When I eat vegetables I usually eat no more than three or four kinds at a time. In the raw condition they have a plentitude of flavors which I enjoy immensely. No condiments are needed! For example, you can't improve upon a really good head of broccoli! It has it all.

Condiments do, indeed, add "zest" to the taste of cooked and processed foods and make palatable those

foods we should not be eating at all (meat, cheese, bread, eggs, etc.) But irritants which goad the taste buds also destroy the taste buds. This calls for a bigger dose of condiments the next time around. It eventually comes to this: We eat food merely as a medium for our condiment addiction! As well as leading to jaded taste buds, condiments are pathogenic. They are really drugs no matter what form they come in—plants (herbs), salt, vinegar or whatever.

Condiments are, according to Webster's, "something added to enhance the flavor of food; especially a pungent seasoning." Note the definition of condiments includes anything that's added to enhance food flavor—pungent seasonings and other things. These other things may include some foods that are perfectly good, such as lemons, limes, tomatoes, sweet peppers, avocados, parsley, celery, Chinese cabbage family members (bok choy, nappi cabbage, etc.) and some other wholesome foods. Even though these foods offer no objection in themselves most of them are not foods you'd try to make a meal out of.

Bananas, grapes, apples and other fruits can be eaten to repletion without any "additives" (i.e., condiments) and they are thoroughly wholesome for us humans. On the other hand, nuts, seeds or avocados, if eaten, should be eaten with a salad. And a salad can always be jazzed up (made tastier) by adding dressings made with some of the foods listed in the paragraph above.

For example, you can eat nuts with a salad containing tomatoes, sweet peppers, celery, bok choy and lettuce. It will be very tasty and super rich in a long list of nutrients, notably vitamins A, C, B, E, and K, and minerals including iron, calcium and trace minerals.

As a rule, reject condiments. Whole raw foods taste fine in themselves, one food at a time. If they don't give you any "kick," then you must give your sensing mechanisms a rest and the opportunity to rejuvenate. Fasting will accomplish this and a raw food diet will do it too. But the taste buds regenerate more slowly while on the raw food diet than when fasting.

[Home](#) > [Lesson 29 - Why Condiments Should Not Be Included In The Diet](#) > Article #2: Salt

## **Article #2: Salt**

The need of salt (concentrated sodium chloride) in human health and nutrition is another of the great myths of modern times.

Salt is a deadly poison, a terrible abusive irritant to human tissue. This can be confirmed by anyone by sniffing salt water and experiencing the terrible burning sensation as the delicate sinus membranes are irritated, by putting salt water into the eyes and experiencing the burning sensation while observing the rush of blood to the eyes to protect their delicate membranes (bloodshot), by putting salt on an open wound and experiencing the terrible burning sensation as the tissue is irritated and destroyed, or by drinking a concentrated salt solution and experiencing vomiting as the body acts to repel this foreign and toxic substance.

Salt is not synthesized or processed in any way in the body and serves no useful purpose. It enters as sodium chloride, it is stored as sodium chloride, it is excreted as sodium chloride. It leaves a trail of destruction from the time it enters until the time it can be excreted.

When excessive salt (that which the body cannot immediately excrete) is deposited everywhere in the fluid medium of the billions of living body cells causing extreme irritation, injury and death to the cells, the cells send forth a desperate SOS signal and the person gets thirsty and drinks a lot of water. This water is carried by the blood and deposited in the tissue fluids to dilute the devastating effects. This results in excessive body fluids, edema.

The body takes every opportunity to excrete this salt—constantly through the urine, at even limited or

almost no exertion by profuse sweating, through crying (tears), etc.

The salt deposits throughout the body cause cells to contract and discharge their life fluids and other vital elements resulting in hardened tissues, shriveled blood corpuscles, hardened arteries, arthritis, ulcers, blindness and distorted vision, hyper-aesthesia of the nerves, high blood pressure, tumors, cancer, psoriasis, neuritis, heart defects, extreme edema and innumerable other degenerative conditions too numerous to list.

In one experiment one of the authors ate typical restaurant salads (with the *usual* amount of salt in the dressings) for one meal and supplemented the salad meal with a few "no salt added" crackers (containing only whole wheat flour and salt in the baking of the crackers themselves) with commercial old fashioned peanut butter which contained only ground peanuts and salt. The next day his one-meal for the day consisted of his usual fresh vegetable salad without any dressing or seasoning supplemented by a bowl of commercial soup containing the usual amount of salt plus some of the same kind of crackers and peanut butter eaten the previous day.

The author's thirst became very pronounced during both days and he drank a considerable quantity of distilled water (his only drink).

The results of only this relatively small amount of consumed salt were astounding. The body retained a great deal of liquid to dilute the harmful irritation of the salt and resulted in the gain of eight pounds in body weight in only 2 days. In addition the absorption of so much water to counteract the salt damage resulted in a much less than usual amount of liquid in the feces leading to a drying-out or compacting effect as the first signs of constipation—a condition the author never experienced during eight years of a salt-free diet.

In addition to the above effects, signs of indigestion and 'heart burn' occurred after each meal as digestion was impaired, and, since all body cells were affected by the salt, a feeling of dullness and loss of energy resulted—conditions which never occurred during many years of salt-free dieting. Other noticeable effects were the puffing and bloating of the face and around the eyes.

The two-day (only two meals) experiment was so extreme in its negative effects that the author ended it and resumed his regular *no-salt* diet. It required approximately two days for his body to eliminate the accumulated salt and water and return to its normal weight and health.

Salt is a true anti-biotic (against all life, a killer). It was formerly used as an embalming agent. It is used today as a 'preservative'—killing the bacteria (life) to prevent the natural decomposition of dead organisms.

Cramps initially experienced as salt is removed from the diet or rapidly excreted from the body are nothing more than "withdrawal symptoms."

A healthy person on a salt-free diet will experience these same cramps if he eats salt.

Salt eating is an addiction begun prenatally and shortly after birth as the parents force salt into the baby to the extreme repulsion and disgust of the child. After a few weeks of forced eating the baby's body becomes so weakened that it forms a craving and addiction. This continues throughout its life.

In order to fully understand the disaster of salt eating, let's briefly follow the path of salt from the time it enters the mouth until it is excreted from the body. Remember, salt has *nothing* to do with the sodium needs or excesses of the body. Salt is sodium chloride first, last and always from the time it enters the body until the time it is discharged. If it were broken down into its primary constituents, sodium and chlorine, as it passed through the body the tragedy would be complete since both inorganic sodium and inorganic chlorine are highly destructive to life and would immediately render a human lifeless.

As the salt enters the mouth in food or drink (or as a deadly salt 'pill') the *cells* of the lips and lining of the mouth (including gums and tongue) are severely irritated, with many killed and the rest seriously weakened.

In a *healthy body* the first line of defense will be instantly activated with a severe and intolerable stinging and burning sensation as the tissue cells are destroyed and the irritation and distress is imposed upon nerve cells. The natural response to such sensation is to spit out the substance responsible for it so that the destruction will not proceed any further. A weak, unhealthy, salt-addicted and taste-perverted body is so deprived and depressed in its defensive capabilities that it not only tolerates but also demands more of the destructive addictive substance.

The cells of the mucous membrane of the throat, esophagus and stomach are the next to suffer the tragedy of death and destruction. As the irritant moves into the stomach the body's second line of defense goes into action.

A healthy body will instantly signal a sensation of nausea and trigger violent contractions of the stomach to cause vomiting and prompt elimination of the salt. A weak unhealthy body will tolerate the irritation and permit it to continue its journey of destruction as some of it is absorbed (assimilated) into the mucous membrane tissue and thence into the bloodstream, and the rest is emptied into the duodenum.

Upon reaching the duodenum, cellular distress is once again repeated. Since the trap door from the stomach has closed the only way for *prompt* discharge of the salt poison is through the intestines and bowels. A normal healthy body will respond with violent contractions of the intestinal muscles which produce a profuse flow of fluid from the mucous membranes to dilute the salt irritation and a rapid propulsion of the salt solution, and everything (all other ingested substances) suspended in it or ahead of it, through the intestines for a violent watery discharge from the anus (diarrhea). A weak unhealthy body will of course fail to actively respond to the salt, and the salt solution and imperfectly digested foods will be absorbed (assimilated) through the intestinal walls and thence into the bloodstream.

At this point the healthy body has rid itself of the salt irritant by spitting it out, vomiting it up and/or excreting it in the form of diarrhea. The weak unhealthy body, on the other hand, has dully accepted the poison and passed it through the stomach and intestinal lining, destroying and injuring millions of cells as it goes. All digestive tract tissue cells have suffered as have all involved blood and lymph capillary cells. The blood carries the salt all over the body creating havoc with every cell. The kidneys which normally filter out small amounts of salt which accidentally accompany digested food into the blood are not equipped to handle large amounts since its own cells are destroyed and injured by the irritant. The liver, which filters and chemically detoxifies many poisons and toxins tries but is helpless to do anything with the very stable and strong sodium chloride molecules and suffers severe damage as the salt passes through it. The heart suffers. The brain suffers. *All* body cells suffer.

Once the salt is trapped in the body's circulating fluids the body response is one of extreme thirst as the cell population screams and cries for relief from the destructive foreign irritant. Most of the fluids consumed by the person are quickly assimilated and dilute and expand the volume of blood plasma, resulting in higher blood pressure and pulse rate. This in turn forces more fluid into tissue spaces to dilute salt concentrations in an effort to relieve cell distress. The fluid accumulates and remains as edema.

The trail of distress, destruction and tragedy is total, having adversely affected every cell in the body. All surviving bodily defense mechanisms are activated to eliminate the salt through tears, sweat, urine, and mucus (excreted in the digestive and respiratory tracts).

More consumed salt intensifies the progressive destruction and deterioration of cells and leads to functional and structural failures through the body.

### **Article #3: Here Are Some of the Reasons Why You Should Not Use Condiments**

1. Most condiments have no food value in themselves.
2. Most condiments are partially or totally indigestible.
3. Condiments are eaten for entertainment, not nourishment. Eating purely for entertainment's sake is, as a rule, unwholesome, though, to be sure, proper foods are not only nourishing but also a delight to the palate.
4. Condiments interfere with the digestion of the foods with which they are eaten, sometimes making a whole meal indigestible. Fifty percent of all meals eaten in America end in indigestion. Condiments share a large part of the responsibility for this.
5. The poisonous elements of condiments (such as the mustard oil of onions, garlic, shallots, mustard, etc. or the allicin of garlic) cause injury in the body if absorbed, especially to the organs of purification and detoxification, such as the liver and kidneys.
6. Our ability to savor flavors is destroyed by condiments. That which overly excites our taste buds slowly destroys our sense of taste.
7. Condiments cause disease! Headaches, high blood pressure, edema and a long list of other conditions are directly traceable to such condiments as MSG, salt, vinegar, etc.

### **Article #4: Using Condiments Is Like Wearing Makeup By Marti Fry**

Makeup is used by many women (and some men) for several reasons. It highlights the eyes with eyeliner, mascara and/or eyeshadow; the cheekbones with blusher and the lips with lipstick. Foundation, usually a flesh-colored liquid, is used to give an even and unblemished appearance to the entire face.

Many of us are aware that the "natural look" is better, both aesthetically and health-wise. Irritating, often carcinogenic, substances on delicate facial skin and near the eyes and on the eyelashes are unnecessary and phony.

The healthy glow that comes from plenty of sunshine, exercise and wholesome foods; a loving disposition and enough sleep, rest and relaxation, mirrors true health. A healthy person is a beautiful person. Makeup is used to give the false impression of healthful beauty.

If you wear make-up but decide to stop using it, it may take you a while to get used to the "new you."

At first you might not like the natural you because you're not used to it. But in time you'll see the phoniness of the makeup on other people as repulsive, not attractive as it used to seem.

Condiments give a very similar effect to foods as makeup does to faces. They give enhancement that is false. They make the foods seem better-tasting than they really are. With condiments you can eat low-quality or cooked foods and try to fool your taste buds into thinking they're getting something really good.

Condiments, like makeup, are irritating and harmful and often carcinogenic. You would be much further ahead to purchase higher-quality foods and eat them in their uncooked state. The foods of our natural biological adaptation are wonderful and don't need seasonings. Likewise, you are attractive naturally and don't need make-up to enhance your appearance.

## Lesson 30 - Sugars And Other Sweeteners May Be Worse Than Bad

- [1. Introduction](#)
- [2. Refined Sweeteners](#)
- [3. Sugar: Where Does It All Come From?](#)
- [4. The Cousins of Sugar](#)
- [5. Some Final Thoughts about Sugars](#)
- [6. Questions & Answers](#)
- [Article #1: Why Honey Is A Harmful Food By T.C. Fry](#)
- [Article #2: More About Honey By T.C. Fry](#)
- [Article #3: Blackstrap Molasses: Super Junk Food By T.C. Fry](#)

### 1. Introduction

#### 1.1 The Sweet Drug

It's a white crystalline powder. It was originally smuggled in from the Far East and was sold at the equivalent of \$12,000 per pound. Its early users soon became addicted. Gradually its use spread throughout the population. At first it was a luxury for the rich, but gradually it was produced in large quantities at cheaper prices so that anyone could afford it.

The health of all its users deteriorated rapidly. Not only did they suffer physically from sugar use, but their mental and emotional states were disturbed. They became irritable, sickly, obese and borderline schizophrenic.

The white powder was not cocaine or heroin—it was sugar.

Today the average American eats his or her weight in sugar every year. The typical American eats *50 teaspoons* of sugar each day, most of it hidden in processed and packaged foods. Probably more health problems can be traced to sugar use than any other single item eaten today.

#### 1.2 Your Sweet Tooth

How did America's deadly love affair with sugar begin? Why is it so bad for you? Most people shrug off the warnings about sugar and continue to use it. "I have to feed my sweet tooth," they say. "I crave sweets. It must be natural or I wouldn't want them."

And to a certain extent, they're right. It is natural to desire sweet foods. You should feed your sweet tooth, but you should eat the foods naturally sweet in wholesome sugars—fresh fruits. In a natural state, our diet would consist of a large amount of fresh fruits and some vegetables. In nature our sweet tooth would be well fed.

However, in the last two hundred years *refined* sugars have gradually replaced the *natural* sugars in our diet. Instead of grapes and apples, we eat corn syrup, saccharin and cyclamates to satisfy our natural

desire for sweet fare.

[Home](#) > [Lesson 30 - Sugars And Other Sweeteners May Be Worse Than Bad](#) > 2. Refined Sweeteners

## 2. Refined Sweeteners

Refining means to make "pure" by a process of extraction or separation. Sugars are refined by taking a natural food which contains a high percentage of sugar, and then removing all elements of that food until only the sugar remains.

White sugar is commonly made from sugar cane or sugar beets. Through heating and mechanical and chemical processing, all vitamins, minerals, proteins, fats, enzymes and, indeed, *every* nutrient is removed until only the sugar remains.

Sugar cane and sugar beets are first harvested and then chopped into small pieces, squeezing out the juice which is then mixed with water.

This liquid is then heated and lime is added. Moisture is boiled away, and the remaining fluid is pumped into vacuum pans to concentrate the juice. By this time, the liquid is starting to crystallize and is ready to be placed into a centrifuge machine- where any remaining residues (like molasses) are spun away.

The crystals are then heated to the boiling point and are passed through charcoal filters. After the crystals condense, they are bleached snow-white, usually by the use of cattle bones.

During these refining processes, 64 food elements are destroyed. All the potassium, magnesium, calcium, iron, manganese, phosphate, and sulfate are removed. The A, D, and B vitamins are eliminated. Amino acids, vital enzymes, unsaturated fats, and all fiber are gone.

To a lesser or greater degree, all refined sweeteners such as corn syrup, maple syrup, etc. undergo similar destructive processes. Molasses are the chemicals and deranged nutrients that are a byproduct of sugar manufacture.

### 2.1 What Happens When You Eat Refined Sugars

When you eat a refined carbohydrate like sugar, the body must take vital nutrients from healthy cells to metabolize incomplete food. Sodium, potassium, magnesium, and calcium are drawn from various parts of the body to make use of the sugar. Often so much calcium is used to neutralize the effects of sugar that the bones, which are the body's storehouse of this mineral, become osteoporotic due to the withdrawn calcium. The teeth, too, are likewise affected and they lose their components until decay occurs and hastens their loss.

When sugar enters the stomach, glutamic acid and other B vitamins are denied to the body. The loss of these specific vitamins results in a confused mental state and a tendency to become sleepy during the day.

Since refined sugars are removed from their natural sources (which contain the necessary nutrients for their metabolism), sugar-eating causes the body to deplete its own stores of various vitamins, minerals and enzymes. *Not only does sugar provide no needed nutrients, it causes the body to rob itself of already present vital elements.* Sugar is both an imposter and a thief.

If the body is lacking the vital nutrients used to metabolize sugar, the result is failure to properly handle and expel poisonous residues such as lactic acid. These wastes accumulate through the brain and nervous system, which in turn accelerates cellular death. The bloodstream becomes overloaded with

waste products, including incompletely metabolized sugar, and symptoms of carbonic poisoning result.

All of the untoward effects of refined sugar metabolism play havoc with the mind and emotions as well as the body. Research studies have demonstrated a link between juvenile criminal behavior and sugar consumption. A majority of the nation's prisoners are "sugarholics" and erratic emotional outbreaks often follow a sugar binge. As early as the 1940's, Dr. John Tintera discovered a relationship between sugar-eating and schizophrenic behavior, as well as other mental illnesses. The effects of sugar-induced depression are well documented in William Dufty's book *Sugar Blues*.

The endocrinologist John W. Tintera was very emphatic in describing the relationship between sugar and the whole person. He said: "It is quite possible to improve your disposition, increase your efficiency, and change your personality for the better. The way to do this is to avoid refined sugar in all forms and guises."

## **2.2 The Sugar Diseases**

Sugar usage has been associated with so many different diseases and metabolic disturbances that it would be difficult to discuss them all in this lesson. However, four of the more common ailments related to sugar consumption can be briefly covered in this lesson. The reader interested in finding out more about the relationship between sugar and disease should consult the book *Sweet and Dangerous* by Dr. John Yudkin.

### **2.2.1 Tooth Decay**

The connection between sugar and tooth decay is probably better known than any other hazard of sugar consumption. Sugar eating contributes to tooth decay because its metabolism by the body requires extra calcium to be drawn from the bones and teeth, thereby weakening the teeth and making them susceptible to decay. Not only white sugar, but all refined carbohydrates have been implicated as a cause of tooth decay.

### **2.2.2 Obesity**

Sugar makes you fat because it supplies only calories, thus causing the body to overeat to obtain its needed nutrients. When you fill up on foods high in sugar, the body must have additional foods (and consequently calories) to get the nutrients it needs.

One pound of apples contains 263 calories, whereas one pound of candy typically has about 1800 calories. A chocolate bar has eight times as many calories as does a banana, ounce for ounce.

Fruit also supplies fiber and bulk to help make you feel "full." Sugar is fiber-free; you'll never experience a sense of physical fullness even after eating two cups of sugar. Consequently, you can overeat on sugar very easily.

If Americans would just eliminate sugar and all refined sweeteners from their diets, they would experience dramatic weight loss.

### **2.2.3 Diabetes and Hypoglycemia**

Diabetes is the failure of the pancreas to produce adequate insulin when the blood sugar rises. Concentrated amounts of sugar cause a rapid rise in blood sugar. Eventually the pancreas can be worked to exhaustion trying to compensate for the unnaturally large amounts of sugar introduced into the body by way of white sugar and other concentrated sweeteners.

In a study of 16,000 people in the Mideast, Dr. Aharon Cohen discovered that among a population who had no past history of diabetes in themselves or in their immediate families, a significant percentage of them developed the disease after they introduced white sugar into their traditional diets.

Sugar-eating has also been associated with another metabolic disease, hypoglycemia. Hypoglycemia occurs when the body overreacts to the amount of sugar in the blood, and too much insulin is released. This condition often results when people have eaten concentrated amounts of sugar on a regular basis, and have "fooled" the pancreas into over-responding too often to the sugar level in the blood. Refined sugars are a no-no for hypo-glycemics and diabetics.

#### **2.2.4 Heart Disease**

In countries where there is a high amount of sugar consumption, there is also a high incidence of heart disease. The theory behind this is that high amounts of sugar cause the insulin in a body to convert blood glucose (sugar) into fatty acids and triglycerides (a kind of blood fat). People on a high-sugar diet develop a significantly higher level of fats in their blood than those who eat no sugar. This high fat content in the blood is believed to be related to the development of atherosclerosis. Sugar may also contribute to heart disease by increasing the blood pressure-raising effects of a high-salt diet.

### **2.3 Sweet Lies: The Sugar Defenders**

Since sugar is a totally useless, destructive, addictive drug that is directly responsible for many debilitating diseases, why is its use tolerated or allowed? Our government shows little sympathy for the pushers of cocaine, heroin, amphetamines and other white powder drugs. Why then are food manufacturers allowed to dose their products with a sweet white poison that kills more people than all the illegal drugs combined?

Sugar is a cheap additive and food filler. As prices of raw food materials have increased, manufacturers of convenience and packaged foods add more and more sugar as an inexpensive extender. During the 1960's, for instance, the amount of sugar used in processed foods *doubled*.

Clearly there is a strong economic basis for putting so much sugar in packaged foods. The food processors and sugar industry have sought to justify this practice by hiring various spokesmen who defend sugar as an acceptable food. Hundreds of thousands of dollars are spent each year in a propaganda effort by the food and sugar industry to defend and promote the use of this refined sweetener. Advertising alone can sometimes convince the public that a harmful substance, like sugar, might have some legitimate use in foods.

Even twenty-five years ago, I remember seeing an ad for Baby Ruth candy bars that stated, "For QUICK ENERGY eat Baby Ruth candy! It's full of dextrose!" Dextrose is simply another refined sugar made from corn starch, no better than white sugar. Sugar has always been defended as a food on one basis alone: it is a "fast fuel"; it gives you a "surge of energy" and "needed calories."

Sugared cereals were promoted for breakfast a few years ago because they were "full of instant energy to start your day." Finally the government cracked down on the manufacturers for so unashamedly pushing their sugar products as something that might be beneficial. Sugar has always been defended and promoted on the fact that it has calories. That it does, and absolutely nothing else.

Consuming these nutrient-empty calories is dangerous—it's like racing a car on high-octane gas without any oil or water in the vehicle. You'll go fast for sure (ever notice a person who is jumped-up on sugar?), but you'll burn out in a very short time.

Still, sugar-cereal manufacturers, fast-food operators, and the processed food industry have to show a profit, and if it's by deceiving the public, well they can always find a person with credentials eager to sell their services.

Consider these amazing statements by Dr. Frederick Stare of the Harvard School of Nutrition:

"Calories are energy, and I would recommend that most people could easily double their sugar intake daily. Sugar is the cheapest source of food energy, and I predict it will become much more prevalent in the diets of the world. People say that all you get out of sugar is calories, no nutrients. Like many foods,

I expect it to be fortified in the future. There is no perfect food anyway, not even mother's milk."

Can you picture this someday? "NEW! Fortified sugar, with vitamins A, B and C added! Better than Mother's Milk!"

Readers should be aware that the Sugar Foundation regularly contributes large amounts of money to Dr. Stare's department of nutrition at Harvard University.

There will always be sweet lies about sugar and refined sweeteners. There will always be defenders who can be had for a price. But the truth remains: sugar will kill you just as surely as anything you can eat.

Out of all this sugar, 20% of it is consumed in soft drinks alone: Many breakfast cereals are 40% to 50% sugar. The following table can give you a general idea of how much sugar is "hidden" in food.

[Home](#) > [Lesson 30 - Sugars And Other Sweeteners May Be Worse Than Bad](#) > 3. Sugar: Where Does It All Come From?

### 3. Sugar: Where Does It All Come From?

#### 3.1 Hidden Sugars In The Diet

Most people do not know that they regularly eat large amounts of sugar. "I never add sugar to my food or drinks," they say, "so how can I be getting that much sugar?"

Actually, over three-fourths of the 128 pounds of sugar most people eat each year is in processed foods. You never see it and you have no control over the amounts added. Sugar is used in packaged foods to prevent spoilage, to retain moisture, to maintain texture and appearance, and, of course, as a sweetener. It's an all-around, cheap filler.

So how much "hidden" sugar is in the American diet? About one-third of a pound every day or about 600 calories. One-fifth or more of the total food intake each day comes from refined sugars.

Food	How Many Teaspoons of Sugar?
Cherry pie (1 slice)	14
Soft drinks (16 ounces)	10
Chocolate milk (1 cup)	6
Canned peaches (2 halves)	4
Jelly (1 tablespoon)	3
Candy bar	18
Fudge (1 square)	4

Chewing gum (1 stick)	.5
Doughnut (1)	4
Cake (1 slice)	15
Cookie (1)	1
Icecream (1 cup)	12

The foods in the preceding table are only some of the more well-known sugar-containing foods. Many processed and packaged foods, however, contain sugar, such as most canned vegetables, frozen fruits, breads, food mixes and additives, baby food, salad dressings, peanut butter, and almost any food sold on the grocery shelf.

Foods prepared in restaurants and fast food places also may contain high amounts of sugar. French fries, for example, are often soaked in a sugared solution before they are frozen and shipped.

### 3.2 How To Avoid Refined Sugars

So, how can you eliminate sugar from your life? Simple. Buy no processed or packaged foods, be careful when dining out, and never add it to any foods or drinks you prepare.

Don't worry about "healthful" substitutes—there aren't any. You don't need refined or unrefined sweeteners in any form. You don't need to gradually taper off or reduce your refined sugar intake. You can stop immediately, today, and suffer no withdrawal effects.

Sugar use is indefensible. Not only should it be avoided, but it never should have been introduced into the diet in the first place.

Although we have been discussing common white table sugar, there are several other refined and unnatural sweeteners and sugars that you should also eliminate for optimum health. Some are the more common "health" substitutes for white sugar, such as brown sugar, raw sugar and maple syrup. Some are the more recently introduced artificial sweeteners such as saccharin and cyclamates. Others are the close sugar-relatives, like dextrose and corn syrup. And one is that favorite food of health enthusiasts—honey. Let's now look at the other sweeteners in the diet and see how they are harmful to the body.

[Home](#) > [Lesson 30 - Sugars And Other Sweeteners May Be Worse Than Bad](#) > 4. The Cousins of Sugar

### 4. The Cousins of Sugar

Often in "health" food recipes, you'll see the use of *raw sugar* or *brown sugar* in place of white sugar. These two sugars have a bare minimal amount of vitamins and minerals—almost none, actually, but still more than white sugar. Brown sugar is just white sugar colored with a little molasses and raw sugar is simply white sugar that may be missing one of the many refining steps that all sugars go through. Another partially refined sugar is *turbinado sugar*.

All of these "cousins" are also sucrose—the same as white sugar, and the differences between all of them are so slight as to be indistinguishable. It's like arguing what will get you the least drunk—whiskey

or scotch. The use of these sugar cousins is usually confined to those people who already know better than to use white sugar in the first place, but they attempt to assuage their guilt by using these equally harmful substitutes.

#### **4.1 Sugar From Corn: Dextrose and Corn Syrup**

Made from cornstarch, *dextrose* (also known as glucose) is a leading contributor to the adulteration of food. Dextrose is mixed into a wide variety of processed foods. As early as the 1920's, Dr. Harvey Wiley stated that flooding the stomach with dextrose creates an artificial situation that would require an additional half-dozen pancreases for our body to cope with it. The sugar refining interests influenced Congress so that dextrose (or glucose) was allowed to remain a legal food additive.

The liquid sugar form made from cornstarch is called *corn syrup*. It, too, is a widely popular food additive used in items such as frozen vegetables, pancake syrups, wines, and even aspirins.

Corn syrup is usually added along with salt, sodium citrate, citric acid, algin derivative, and artificial flavorings and colors, so the consumer gets a triple-deadly dose of food additives.

#### **4.2 Fructose—the Sugar From Fruits**

Fructose is commonly known as "fruit sugar" and is the predominant sugar in fresh and dried fruits. Along with grape sugar, dextrose, and levulose, fructose is classified as a monosaccharide carbohydrate with the chemical formula C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>.

Fructose is a natural sugar, and it is found in many fruits along with wholesome nutrients such as vitamins, minerals, enzymes, etc. It is the energy component of fruits, and the liver converts it to *glucose* which is then either used for immediate fuel needs or is stored as *glycogen* for later energy use.

For each molecule of fructose, the body forms one molecule of glucose, and thus the energy needs of the body can be efficiently met by natural fruit sugars.

Fructose when it is consumed in *whole fruits* is a wholesome fuel. When it is made into a *refined powder* or separated from the sucrose of which it is a part, fructose is a disruptive toxin.

In recent years, fructose has increasingly been refined and made into a fine white powder and sold as a "safe", sugar substitute. While fructose use is promoted because of its presence in fruits, it is no different from white sugar because it is refined from white sugar.

In its refined state, fructose is a concentrated and toxic carbohydrate that has been stripped of all vital nutrients. It is a fuel devoid of nutrients, and is certainly not "health promoting."

Refined fructose is very soluble and is absorbed by the mucosal cells of the intestinal tract at a rapid rate. This quick absorption fructose, without any co-existing nutrients, can cause the same harm as sucrose, or common white sugar.

Refined fructose intake can result in several toxic effects, such as: disrupted liver protein synthesis, acute hypoglycemia, elevation of blood fats, and general metabolic disturbances.

When you eat fructose along with other nutrients in the form of fruits, you are receiving a high-quality and complete body fuel. When refined and stripped of nutrients, "pure" fructose becomes a disruptive toxin in the body.

#### **4.3 Maple Syrup**

If it comes from a tree, it must be okay for you to eat, right? Wrong. While maple syrup comes from a natural source (like fructose and sucrose for that matter) and it does contain some nutrients, it still is a nutritionally unbalanced food. It undergoes high-heating and adulteration in its processing and manufacture.

Besides being concentrated and deadened by high heat, maple syrup may also be contaminated by paraformaldehyde which is used during the tapping process to destroy bacteria. Formaldehyde compounds are poisonous and certainly should not be eaten in food.

Maple syrup is rarely a pure food; other sugars and sweeteners may be mixed in and added without telling the consumer. Sugar, corn syrup, and other refined sugars can be used to stretch out the more expensive maple syrup. Maple syrup is not a pure and unprocessed product; high heating alone makes it inferior and undesirable in an optimum diet. The sugars present in the syrup have become concentrated beyond their natural strength by the introduction of heat in its manufacture. Maple syrup seems to be especially popular with vegans (people who eat no animal products, such as honey), however, they should be aware that maple syrup is still a refined sweetener that has no proper place in the human dietary.

#### **4.4 Molasses**

Molasses is another highly heated sweetener like maple syrup. This food item is discussed in detail in another lesson as an example of a "junk food" product, so we will not go into detail in this lesson about it. Its use is chiefly promoted because it is a concentrated source of minerals (usually iron); however, the same process which concentrates the minerals (high heat, etc.) also destroys them. Further, pesticides and chemicals used in growing and processing are concentrated in the product. It becomes a heated, dead food that is a storehouse of toxic chemicals as well as toxic minerals. In addition, the high-sugar content of molasses is caramelized. It is poorly handled by humans. Molasses has no benefits. It is pathogenic from other nutritive aspects.

#### **4.5 Honey—How Healthy Is It?**

What could be more natural than honey? Health seekers have sung its praises for years, and it is promoted as a beneficial, healing food. Is honey a perfect food, easily digested, and toxin-free as so many writers would have us believe?

Actually, honey is little better than most of the other refined sweeteners and sugars. True, it can be had with little processing and no heating, but does that make it a natural food for man? The truth is that honey contributes to tooth decay, obesity, diabetes, and other diseases that white sugar use has been linked with.

Honey is defended as a wholesome food because it has been used for a long period, much like milk and dairy products. Like milk, honey is a food that is produced by an animal to *feed its own species*. It is not a natural food for man—it is a natural food for bees.

Honey is produced by the bees modifying the nectar of flowers with formic acid produced within their bodies. The bees regurgitate the honey after mixing. Water is evaporated from the honey by air currents generated by the wings of worker bees. The nectar is usually vomited up several times before it is mixed enough with the bees' own preservative secretions.

The honey is also produced with various enzymes to meet the special needs of the bees themselves; consequently, the changes that occur in the production of honey are not amicable to man's metabolism.

Bees are often robbed of their food product and forced to live on sugared water by their keepers. Often, poison sprays such as carbolic acid and benzaldehyde are sprayed into the hives (and onto the honey) to chase the bees away so that they may be robbed.

Most commercial honey is heated, filtered and processed. Even bees cannot live on heated honey for long. If fed such honey, the bees sicken and die. Honey may also be adulterated with white sugar syrup, corn syrup and other additives, so honey is rarely the "pure" product it's advertised to be.

Honey is almost pure sugar and water. There is a minute amount of mineral material in honey, and it is

this mineral content that health enthusiasts point to as a justification for using honey instead of white sugar. This argument is faulty because the mineral content is so low that you would need to eat 200 tablespoons of honey a day to meet your calcium requirements, 91 tablespoons for your potassium needs, and 267 tablespoons to satisfy your phosphorous needs. Obviously honey has minimal nutritional value for humans.

Honey has also been shown to destroy teeth even faster than white sugar. A study at Oregon State University demonstrated that some honeys may contain cancer-causing substances that the bees have extracted from certain flowers. Other honeys have been associated with botulism, an often fatal form of food poisoning.

Honey is not for the health-seeker; indeed, it is not for any human being. Honey is not for the birds either—it's for the bees. They made it, let them eat it.

#### **4.6 Sugars From Coal: Cyclamates and Saccharin**

All the sweeteners discussed so far have been derived from plant sources either directly (corn syrup, white sugar, maple syrup) or indirectly (honey). Two popular sugar substitutes, however, come from coal-tar.

In 1879, a substitute for sugar was discovered that was 300 times as sweet as white sugar. Called *saccharin*, a pill the size of a pinhead can sweeten a cup of coffee.

In 1970, researchers at the University of Wisconsin reported a link between saccharin use and cancer of the bladder. Based upon this and other studies, the F.D.A attempted to ban the sweetener in 1977. A public uproar developed, however, because with the removal of saccharin from the market, there would be no way for diabetics and other people on a sugar-restricted diet to obtain concentrated sweeteners (or so the reasoning went). Congress therefore imposed a ban outlawing the removal of saccharin but required stores to post a notice indicating that products containing saccharin were sold there.

Needless to say, this artificial sweetener is dangerous enough to be banned, and should be avoided by ail people.

A relative of saccharin is a group of sweeteners known as *cyclamates*. Cyclamates were promoted in the 1950's as a way for obese Americans to satisfy their sweet tooth without paying the price in calories. Cyclamates are 30 times sweeter than sugar and had been manufactured as early as 1937.

By 1969, about 175 million Americans were consuming 20 million pounds of cyclamates every year. In the next few years, medical reports stated that injury to fetuses, diarrhea, and damage to kidneys, the liver, the intestinal tract, the adrenal glands, and thyroid could be traced to cyclamate use.

Cyclamates were finally banned in 1969, about 14 years after their harmfulness was first revealed. Unfortunately, the refined sugar products, equally dangerous in their own way, are still allowed to be sold. Perhaps in a few more years, an enlightened public will demand the removal of white sugar and other sweeteners from their foods as well.

[Home](#) > [Lesson 30 - Sugars And Other Sweeteners May Be Worse Than Bad](#) > 5. Some Final Thoughts about Sugars

#### **5. Some Final Thoughts about Sugars**

Why do human beings want sweet foods in the first place? What are some safe ways to satisfy our sweet tooth?

Dr. Gary Beauchamp of the University of Pennsylvania stated that our sweet taste has served us well in the course of evolution. Our sweet tooth allowed us to know when foods like fruits and berries were ripe and ready to eat. It guided us to the selection of naturally wholesome foods. Our sweet tooth and desire for sweet foods is perfectly natural and desirable.

In recent times, however, our sweet tooth has become perverted. Dr. Beauchamp says that now "we've separated the good taste from the good fun," and our sweet tooth is leading us astray with the introduction of refined and supersweet artificial sugars in the diet. Actually, refined sugars and the like achieved their stronghold first in countries where there was not an abundance of fresh sweet fruits. White sugar has served as a poor and dangerous substitute for fruits in climates where fruits were not readily available. Fortunately in today's world, we are now able to satisfy our sweet tooth naturally, but we've been deceived so long by the artificial and refined sugars that it takes some time to readjust our taste.

Once refined and artificial sweeteners are eliminated from the diet, you will gradually re-acquire your naturally discerning taste and avoid all such refined and unnatural sugars with little effort. They will cease to appeal to you as you re-discover the natural sweetness and goodness of fresh fruits.

Humans naturally seek to eat sweets. Thus the act of sweetening foods is to meet our biological adaptation to sweet fruits.

One of the foremost evils of using sweeteners is on the grounds of incompatible combinations. Anything sweet naturally does not require sweetening and anything that we sweeten is intrinsically incompatible with sweets.

We are not natural fat or oil eaters. We get this incidentally but sufficiently from our proper foods of fruits. We are not natural protein eaters. We obtain our needs incidentally but sufficiently from fruits. We are not starch eaters. We have a limited capacity to digest starches—a capacity that was developed very poorly—sufficient to handle starches incidental to fruit-eating. The ptyalin of the mouth is so poor in its digestive capabilities that it digests less than 5% of the starch. Final digestion of starch must be carried on with pancreatic amylase in the small intestine.

While simple sugars such as fructose and glucose require no digestion, sucrose must be broken down into these respective monosaccharide components before absorption can occur.

Mixed with fats, starches or proteins, all sugars, simple or more complex like sucrose, are an abominable combination. The sugars are held up while the more complex foods are being digested. They quickly ferment, forming vinegar and alcohol. This is toxic enough in itself but the digestion of the foods with which they! are mixed is then vitiated so that marked indigestion occurs.

There are no counts justifying the use of sweeteners. Our yen for our natural sweet fare should be sated with our *natural* sweet fare.

Remember: when you eat fruits, you not only satisfy your sweet tooth, but you supply the body with the finest fuel available along with a storehouse of valuable nutrients and elements. Say good-bye to the sweet imposters, and hello to a new life of health and well-being as you eliminate sugar forever from your diet!

## 6. Questions & Answers

**Well, you've pretty well eliminated any possible sweetener I could use. Isn't there anything we can use to add extra sweetening to our food that isn't harmful?**

If you are having fruit meals, you can add dried fruits for a concentrated sweet flavor. In connection with that, you can also consider date sugar as probably the least harmful of all concentrated sweeteners. Although made entirely from dates, date sugar is still not an optimum food because it is usually dried at a high temperature before being powdered.

Another difficulty with using any added sweetening to foods is that it generally leads to unsuitable food combinations, unless the foods are fruits (which probably don't require extra sweetening in the first place).

If you're eating a proper diet, high in fresh fruits, your sweet tooth will be well satisfied without any concentrated sugars.

**My husband is a diabetic, and we've been using artificial sweeteners instead of refined sugars. We're going to stop now since we've learned about the carcinogenic (cancer-causing) properties of these additives. But can he start to eat a lot of fruit, since he is diabetic?**

Fructose, as it exists in fruits, has a greater advantage for diabetics than other sugars. Unlike other sugars, fructose does not require insulin to get into the liver and the body cells. So when you eat fresh fruits high in fructose (natural sugar), there's no sudden demand for insulin, which diabetics cannot produce in adequate amounts. Similarly, fructose in fruits is also an ideal sugar for hypoglycemics. Remember, don't get this confused with the refined fructose (the white powder) which should not be used by diabetics, or anyone else for that matter.

**I've heard so many good things about honey. I just can't believe it could be as bad for you as you say. We have our own bees, and I think they give us the best sweetener available.**

People who have milk cows frequently make the same statement when they are told about the harmfulness of milk products. People that hunt and kill their own meat also think that because they are getting their product "fresh," it must somehow negate the bad aspects of the food.

I congratulate you on having bees around. They perform a very vital job in the garden and orchard by pollinating these plants. But why do you want to rob them in return and eat a food that was made by the bees for themselves alone to eat? Every species has its own food to which it is uniquely adapted. We humans are best suited for the fresh fruits and vegetables of the earth; that is our physiological nature. Bees are best suited to the honey that they make with their own body secretions.

It often takes a long time for the realization that cow's milk (another animal food) is not suitable for man to eat, even if it is fresh and unprocessed.

The simple truth is that if you are eating a natural and optimum diet of chiefly fresh, raw fruits and vegetables, you will have no desire for a concentrated sweetener like honey in the first place.

**This may sound silly, but what about desserts or candies? Without some kind of sweetening, you take a lot of pleasure out of eating. How could I ever make a cake for instance?**

You're not going to like this answer, but you really shouldn't be eating or making these foods in the first place. I repeat, if you are eating a sufficient amount of fresh or dried fruits throughout the day, you're not going to want cakes, pies, cookies or candy. You can make a whole meal one big "dessert" if you have an all-fruit meal.

People desire pastries and other sweets when they have neglected the fruit part of their diet. However, don't use fruits just as a dessert for a conventional meal; this is a poor food combination. Make fruits a whole meal in themselves once, twice or three times a day. You'll never want pie or cake again once you've re-educated your taste buds.

[Home](#) > [Lesson 30 - Sugars And Other Sweeteners May Be Worse Than Bad](#) > Article #1: Why Honey Is A Harmful Food By T.C. Fry

### **Article #1: Why Honey Is A Harmful Food By T.C. Fry**

It is, of course, true that honey is a wonderful food—for bees! The popularly fostered idea among health seekers that honey is a wholesome, nutritious and natural sweet for humans is fallacious.

Honey is the product of the bee's stomach. The bee ingests pollen from flowers and, in its stomach, mixes it with formic, manite and other acids. Then the honey is deposited in cone cells and, by the wind created by a multitude of bees wings, substantially dehydrated.

Without these acids and the drying, honey would readily ferment and prove unusable for the bee which must have a dependable food supply for up to eight months in some of the harsher climates. Because of these acids and dehydration, honey is impregnable to bacteria. It is rather poisonous in the human digestive tract.

As a food for us honey is woefully mineral and vitamin deficient. Humans require infinitely more food factors than bees.

While honey contains several very desirable sugars, these have been rendered toxic by the protective acids imparted to them by the bees. These acids are the bees' preservatives. Humans do not have the enzymes to break these acids down, as have the bees, and must rob their bodies of vital base-forming minerals to neutralize the acids.

When humans eat honey, it immediately begins to reabsorb moisture from the stomach and stomach flora. It destroys our symbiotic bacterial population wholesale. Several tablespoons of honey makes most people very sick.

In humans honey, more so than cane and beet sugars, is acid-forming and decalcifying. The body draws calcium from its teeth and bones, if necessary, to neutralize the acids *introduced* and *formed*.

Manite acid of honey is a protoplasmic poison. It interacts with protein and from this, forms alcohol, ammonia and carbonic acid.

As eaten, honey is an atrocious food. It is usually added to starches and proteins as a sweetener. It readily ferments when held up in the stomach with other longer-digesting foods. The byproducts alcohol, ammonia and carbonic acid are deleterious to human health.

Honey is, therefore, neither a nutritious nor a safe food. Life Scientists should not use honey as a part of

their diet.

[Home](#) > [Lesson 30 - Sugars And Other Sweeteners May Be Worse Than Bad](#) > Article #2: More About Honey By T.C. Fry

## **Article #2: More About Honey By T.C. Fry**

Ida Honorof publishes a newsletter entitled "Report to the Consumer." She usually goes into a subject in-depth and certainly she is one of the most outspoken persons in America on environmental concerns.

Anyway, in March she published an extensive article about honey. She recommends it in place of sugar. But, to her credit, she gives us a very frank appraisal of honey as a food and points out that better sugars are to be found in organically grown fruits.

First, she points out that, though pesticides are toxic to bees, not all bees succumb to toxic substances and that today's honeys cannot be called organic in any sense—most honey has pesticide residues in it. Bees gather this from flowers along with the nectar and pollen.

Then there's the matter of the nutritiousness of honey. It has only minute quantities of nutrients though it has "nutritional merit." Ms. Honorof says, "Many people converted to using honey, often excessively, despite the fact that to the human body, honey is hardly different than refined sugar—remember honey was meant for the bee." Which is to say that honey is not our natural food but natural food for the bee.

She quotes a famed bee specialist, Colonel Clair of Hawaii. Some of the data she quotes turns out to be very revealing, a lot more than honey promoters would appreciate.

First, most beekeepers rob their bees of practically all the honey and substitute for it water and sugar or wastes from candy factories. Anything sweet and cheap is substituted for the honey taken from the bees. The result is diseased bees. Further, the chemical industry has begun furnishing "medicines" or drugs for beekeepers just as they have furnished "medicines" for humans.

We Life Scientists have great concern for bees. They are our symbiotic partners in Nature. And the despoliation of bees must lead to our own—we are very much despoiled and depraved already.

It seems the worst enemies of bees these days are uninformed beekeepers who try to exploit bees to the maximum. They are paid for their hives by orchardists. Then they rob the bees of honey too. That doesn't mean the apiarists are making it rich but it does mean the poor bees are being meanly used, not only to their detriment but to ours! Of course this applies only to most beekeepers who supply in huge quantities the refined honey on supermarket shelves.

Ms. Honorof's article is in many ways revealing. One of the closing highlights is that honey, itself, is practically non-nutritious. It is the pollen grains in the honey that bear most of the nutrient complement.

Colonel Clair, her source of information, cautions against using heated honey altogether. He praises honey for its "antibiotic qualities."

That praise must be, to thinking people, damnation! For antibiotic means "against life." While they mean antibacterial, the word is correct, for an antibiotic is truly against all life.

But the clincher is the final admonition: "Honey must be eaten sparingly, in very small amounts." Our own admonition is: *If anything must be eaten in moderation or sparingly, it should not be eaten at all.*

### **Article #3: Blackstrap Molasses: Super Junk Food By T.C. Fry**

The sales job the aluminum and chemical industries did to put their poisonous wastes, that is, fluoride compounds, into much of the nation's drinking water as a health measure must, by all standards, be called masterful even though fraudulent.

But, by comparison, you must positively applaud the sugar industry in selling its primary waste product to "health consumers" who pride themselves upon their food savvy, fastidiousness and awareness. In fact the sales job done on the "health food crowd" is so good the sugar industry gets more money from their poisonous waste than from the primary product, unwholesome white sugar.

The extent of the esteem in which blackstrap molasses is held merely points up the gullibility, credulousness and generally uncritical thinking with which "awakened" people accept "health claims" if they come from the "right" quarter.

Of course it is fitting that you and I should not have to be concerned with our food any more than the air we breathe. We should be able to accept all the food we eat as uncritically as the animals in their natural habitat eat the foods of their adaptation. *That's the way it should be!* For there are more productive, cultural and joyful pursuits in life than immersing ourselves in concerns about our stomach and what to put into it, our bowels and their business, our liver and its business, etc. Under the circumstances it is proper that we be deeply concerned. But our concern must be bolstered by deeper thinking than that which so readily endears such a pernicious product as blackstrap molasses.

Talk about candy, primarily a white sugar product, being a junk food, it can't even hold a candlestick to blackstrap molasses! Blackstrap is over 50% sucrose itself and that's the least of its drawbacks in the human diet! Anything bad that can be said about white sugar and candy goes double and triple for blackstrap molasses.

With candy at least you have sugar that has gone through only two or three cookings. And the chemicals used in its extraction are in the molasses, not in the sugar. Further, candy often has the virtue of having some nuts or nut butters, fruits, etc. in it. But, nevertheless, candy's reputation as "sugared junk" is well deserved.

But if candy is junk, then molasses is super junk! For molasses has more of the same evils that candy has plus some evils that candy and white sugar never had (unless it contains molasses which some candy and brown sugar does) and it has none of the "redeeming qualities" that some candy has.

I have several "health" publications that go into ecstasy over this "natural health food." A natural health food, mind you! And some mighty big names in the "health field" lend their endorsement—in fact almost all the big names in the popular health field would consider themselves remiss if they had not sung the praises of blackstrap molasses.

Before we get into the nitty gritty of just what blackstrap molasses represents and how this foul-tasting waste product came to be so popular, let's investigate that "natural" angle.

When we speak of a natural food we mean, of course, a natural food for humans.

Now Nature has been, on the scene for who knows how many eons of time. Blackstrap molasses has yet to reach its 300th birthday! *Nature came mightily late in providing us with this wonder food!* Nevertheless, let's put blackstrap molasses to the "natural" test.

1. TO BE NATURAL, a food must be one to which humans have adapted anatomically, physiologically and psychologically.
2. TO BE NATURAL, a food must be delicious to the palate of humans in its natural state.
3. TO BE NATURAL, a food must be eaten and relished in its living or raw state. Humans, like

animals, weren't endowed with cook stoves.

4. TO BE NATURAL, a food must have been nurtured to its finished state by Nature by strictly natural agencies.
5. TO BE NATURAL, a food must appeal to unperverted human gustatory senses, i.e., to our senses of smell, taste and sight such as does a beautiful redolent apple, for instance.
6. TO BE NATURAL, a food can be eaten alone and relished by unperverted palates.

These are only some of the criteria for a natural food of humans. How does molasses stack up against these yardsticks?

1. To begin with, humans haven't been eating molasses long. No adaptation whatsoever could be possible. Psychologically the product has no appeal at all except that we are conditioned to it as we are to other perversions. Children rebel against the stuff, something they don't do with, say, apples or bananas.
2. Molasses is not delicious to any normal palate and is repulsive to most who "eat it for health" reasons. Molasses has no natural state inasmuch as Nature never created such an abomination.
3. Of course Nature did not even get into the act on molasses—it is strictly a manufactured product. To represent that the sugar cane and beets from which it came is reared organically by natural means is a gross absurdity.
4. Molasses has no living state, for Nature did not create it. It is a waste product in the production of white sugar with all its evils plus a host of its own. Molasses is one of the most cooked substances you can buy. As our friends into Yoga would say—it has no prana or life force.
5. Blackstrap molasses is repulsive to our senses of smell of taste and sight.
6. And last, but not least, blackstrap molasses cannot be relished by itself by even the hardest! A proper food of humans can be eaten as a meal. For instance we can make a mono meal of any one of these foods: apples, watermelons, cantaloupes, bananas, grapes, oranges, peaches, apricots, figs, dates, etc. And you can live well on one of these foods alone for several weeks with healthful results. Many people do! Can you imagine trying to live on a mono diet of blackstrap molasses for several weeks? Or some of its syrup cousins, including the highly touted maple syrup and honey?

So much for the "naturalness" of blackstrap molasses. It doesn't meet one single criterium as a natural food for humans. And certainly a food that is not natural to humans cannot be healthful for humans. Moreover, you wouldn't consider putting an unnatural, unhealthful food into your body, would you?

For more detailed information on molasses, see [Lesson 35 - Junk Foods: A Case Study On Molasses](#)

## Lesson 31 - Refined And Processed Foods Are Hazardous To Your Health

### 1. Introduction

Every day the scientists looked in on their cage of mice. Each time one or more dead animals had to be removed from the cage. After about sixty days, more and more mice were dropping dead. One of the scientists looked worried.

"I don't know how much more of this experiment they can take. We may end up killing all of them in the next few weeks if we don't stop."

The other scientist nodded his head. "It seems cruel, I know," he said, "but I think we're discovering something important here. This diet we've got them on should tell us a lot more about proper nutrition—or rather, what poor nutrition can do to an animal."

The second scientist sighed. "You're right. Here's their meal for today."

"The same as yesterday?"

"Yes, and the same as the day before and the day before that. You know that's the only food we're feeding them for ninety days."

The younger scientist took the food and tore it into pieces and dropped it among the mice. They moved sluggishly toward it and sniffed it. Some were huddling in a corner, sick and barely able to move.

He finished feeding the mice their experimental diet. He brushed the crumbs from his hands. "Guess I better get another loaf of bread to feed them again tomorrow. Same brand?"

"Doesn't matter," said the older scientist, "Just so it's white."

After a ninety-day diet of white bread, 40 of the 64 mice were dead. The survivors had developed many of the diseases of "modern" man—heart problems, anemia, and extreme nervous disorders.

White bread, breakfast cereals, flours—all refined grain products contribute-greatly to this nation's ill-health. Yet studies indicate they make up *one-third* of the average person's total carbohydrate intake each day.

#### 1.1 What Are Refined Grains?

A refined grain, or its product, is made by processing a natural whole grain so that some of its nutrients are lost. Flours, breads, cereals, noodles, pastries—almost all grain products have been refined in some way or another.

White rice, corn grits, wheat flour, hominy, a piece of toast, a cookie, the bowl of snap-crackle-and pop

each morning—all are examples of refined grain products. *ALL* are harmful additions to the diet.

## 1.2 Why Are Refined Grains Harmful?

Refined grains and their food products are substandard foods for several reasons:

1. They're excessively starchy—in fact, they're the most starchy foods eaten by humans. All starches, even unprocessed and unrefined ones, are handled with difficulty by our digestive system. When refined, their starchy nature is emphasized.
2. They're almost always eaten in a poor food combination—such as sandwiches, or sweetened pastries, or bowls of cereals. Invariably, they're mixed or cooked with other starchy foods or heavy proteins, or fried in fats.
3. They are acidic in nature, due to their mineral content, and consequently, they acidify the body and predispose it to excessive mucus formation.
4. They are practically devoid of natural fiber and low in moisture, hence constipating.
5. They must be cooked, altered, and otherwise processed before being eaten.

And perhaps most important of all, refined grain products are *nutritionally imbalanced*. It is because of this imbalance that these foods are responsible for several degenerative diseases. Calcium-leaching from the bones and teeth occur because of the altered phosphorous-calcium balance in these products. Sugar and refined grain products are primarily responsible for all tooth decay in this country, as well as the major cause of brittle bones in the elderly.

In natural organic foods that are eaten in their whole and unprocessed state, all the elements for proper nutrition are in their proper balance. This balance is completely destroyed in the refining process of grains.

For example, the mineral cadmium always exists along with the mineral zinc in foods. The zinc acts as a balancing mineral for the cadmium and prevents it from being absorbed in too large amounts by the body. Cadmium, in excessive amounts, is hazardous to human health (it is one of the poisonous elements in cigarette smoke, for instance). When grains are refined, the zinc mineral is destroyed but the cadmium is not; so, you get a massive absorption of cadmium without the balancing effect of the zinc when you eat refined grains.

As another example, both iron and copper minerals are destroyed when grains are refined. Copper is necessary for the utilization of iron by the body to build a healthy bloodstream. Inorganic iron (useless to the body anyway) is added back to the stripped flour, but of course the copper is not. You can't fool around with the natural balance of nutrients in foods, and then hope to restore them or negate the harmful effects created by this processing.

The B-vitamins, vital for the health of the nerves and body, are quickly destroyed by any refining of the grain. Interestingly enough, the body requires B-vitamins to metabolize or use these grain products (which is why they are present in the food in the first place). If these vitamins are removed from the grain products, then the body must rob from the current supply of B vitamins in the body so that these refined grains can be digested.

Not only are refined grains and their products nutritionally deficient and imbalanced, they can also contribute to a loss of vitamins and minerals already present in the body.

Two of the most popular ways of eating refined grains are in the form of bread and cereals. We'll look at these two products in great detail so that we can understand why refined grains have no place in a healthy diet.

## 1.3 Food Processing and Grain Products

Food processing is used to describe everything from home cooking to sophisticated food-manufacturing

processes. Actually, anything we do to alter the original state of food, be it cooking, blending, refining, or adding a hundred chemical ingredients, is a form of food processing.

When we talk about food processing and grains, however, we are mostly concerned with food refining. Refining is the breaking down of a whole food into various parts. Grains, for example, are often eaten in the form of flour products such as breads, pastries, etc. Few people in America eat grains in their whole forms as they are harvested. Whenever foods are eaten in fragmented, refined, or processed form, a lower level of health invariably results.

Food is man's most immediate point of contact with nature. As such, it must be suited to the laws that govern our body. While the human body is a remarkably flexible instrument, it cannot adapt to foods that have been radically altered from their natural form. Grains, as we shall see, are probably not an optimum food for man anyway; when they are processed, refined, and altered, they can become injurious.

When beginning the study of a subject such as this, it is useful to get a historical perspective. Fortunately, one area of food processing has been well documented for several thousand years: bread making. Bread is probably the first refined and processed food product eaten by man. We can understand the effects of refined grains on the body if we study the history of bread-eating from ancient times to the present.

## **1.4 The Early History of Grains**

As long as primitive man could live in areas where fresh food was available for 12 months of the year, he had little need for agriculture. Fruits and vegetables, the mainstay of early man's diet, were well supplied in a semi-tropical environment. Foraging and food gathering were the main methods used to acquire food.

With the changing of the climate and the migration of primitive tribes, new food gathering methods had to be devised. Man needed to find some way to store nutrients for periods of time when no fresh foods were available. Seeds, such as cereal grains, seemed to be one way of solving the food storage problem, and so man became agricultural in lifestyle.

Grains were probably among the first cultivated crops. They were not as tasty or beneficial as the fresh fruits and vegetables, but they could be grown in large amounts for storage in climates where the winters were harsh.

This development occurred only about ten thousand years ago—a very short length in the half-million year or so span of, man: With this growing of grains, cooking developed. If cooking had not started, it is doubtful the cereal crops would have been of much use to man. Cooking, the first food processing, developed simultaneously with grain agriculture.

Early grain processing seems to have consisted of either toasting the whole grain, or heating it up in watery mixtures, such as porridges or gruels.

By the time of recorded history, however, man had learned to process the grains farther and farther until he was finally able to make bread from his crops.

## **1.5 The Loaf of Bread**

Until about 3000 B.C., grains were pounded in mortars to make a rough meal from which the bread could be partially sifted. This meal was then mixed with water and heated to form a porridge.

The Egyptians developed a grinding process in which the grain was crushed between two rolling stones. This allowed the endosperm of the grain to be reduced to a fine flour so that it could be sifted finer and finer from the coarser bran. This produced a flour that was refined enough for baking or bread-making purposes. As you can see, bread is a relatively new food in the diet of man. The loaf of bread, "staff of

life," has only been around for the last five thousand years or so, or less than 1% of man's existence.

The Greeks improved upon the grain-grinding process with rotary grindstones, and by 500 B.C., combined flour mills and bakeries were operating in Athens. Bread was being sold commercially, and already there were different types of bread one could buy (such as coarse barley bread for slaves, wheat for the upper classes, etc.)

It was the Romans, however, who gave us our first "white bread."

## 1.6 The Fall of the Roman Empire

During Roman civilization, flour milling technology rapidly developed, and soon the Romans were making four or five commercial grades of flour. The finest flour, almost a creamy color and not quite as white as that of our white bread, was sold only to the upper classes. Interestingly enough, the wrestlers and athletes of that time were fed the coarser grade of flour "to keep their limbs strong."

Of course the "finer" or more refined flour eaten by the Romans had far less nutritional value and was a more fractured and fragmented food than had been eaten by man until that time. The Romans associated their new white bread with goodness, purity, nobility, and birth. These emotional feelings of refinement, higher living, snob appeal, etc. soon became inseparable from the texture, taste, and appearance of the white bread. As in modern times, the rich or upper class were the first to adopt the highly refined foods as a mark of "class distinction." The health of the Roman upper class degenerated through the years—some blame it on the lead content in their cooking vessels, and others point out their fondness for the new white bread. Whatever the reason, as the health of its leaders failed, the empire itself crumbled.

After the Romans, it was 1500 more years before the "art" of flour refining reached this height again.

So, what can we learn from this bit of history? Have we proven anything, other than that man became increasingly "sophisticated" in this bread-making abilities? Fortunately, we can trace the health of man as he began eating more and more refined products.

## 1.7 Refined Grains and Dental Cavities

By studying the skulls and tooth remains of ancient, man, from 3000 B.C. all the way to the twentieth century, researchers have been able to devise a table showing the amount of tooth decay experienced by man during various time periods. Let's look at the figures:

### Dental Cavities From Ancient Times To The Present

Time Period	Percent of Teeth With Cavities
3000 B.C.	3%
2000 B.C.	4.5%
1000 B.C.	5%
100 A.D. (Roman)	11%
1000 A.D.	5.5%

1950 A.D.	24%
-----------	-----

It is no coincidence that the Romans had more cavities than any other ancient people; they also ate more highly refined flour products. After the "art" of flour refining was lost with the fall of the Roman Empire, notice that dental cavities decreased by half, or almost back to their level before refined flour products were introduced. Then, less than a thousand years later, the cavities' percentage of modern man has increased *five* times over most ancient peoples. Needless to say, there has been an enormous increase in the amount of increasingly refined flour products in the last few hundred years. Do you think there is a connection? Many people do.

As poor as refined flour and bread products have been throughout history, they were still able to support life, if not enhance it. With the nineteenth century, however, the quality of bread became so poor that it was anti-life, or destructive.

In 1826, an experiment was conducted with the newly developed white bread of industrial England. The researchers discovered that "a dog fed on fine white bread *does not live past the 50th day*. A dog fed on the coarse whole bread lives and keeps his health."

## 1.8 Bread Not Fit To Eat

In the nineteenth century, mass production of bread began in earnest. In fact, the first assembly line in the world was devoted to making bread sea biscuits for English crews. This mass production of bread required that the product have good storage qualities.

This extended storage time for bread is the most often cited reason for the amount of refining done to the flour. The nineteenth century miller and baker discovered that the germ of the wheat contains oils and these oils go rancid over a period of time. The germ and the aleurone layers of the grain also contain the major food value of the grain, and these attract rodents and bugs. Remove the nutrients, refine the flour even more, and the rats and insects will leave it alone. *They know what many humans still don't know: that such refined flour products cannot support life and are worse than worthless to eat.*

This removal of the wheat germ and other nutritive factors from the bread as a convenience to the baker and *not* the customer marked the beginning of an era in food production. As bread-making progressed in the 1800s and 1900s, any changes made in the process were always done for the benefit of the *producer*. The consumer just, had to unconsciously adapt his taste to the type of bread that was best suited for mass production and rapid turnover. Bread was the first "technological" food; it was industrial food for the masses, cheap in cost and devoid of nutrition: the first junk food.

## 1.9 A Loaf of Chemicals

Bad as the bread was in the 1800s and through the mid-1900; it became much worse after the end of World War II. The chemical warfare banned in the war in Europe was just transplanted to the bakeries of America as the bread-makers began to slowly poison their customers with all sorts of new additives, bleaches, and preservatives.

Even refined flour still has natural yellow pigments (such as carotene—a precursor of vitamin A). The millers discovered they could remove this color and make their flour even whiter by bleaching it. They started blowing chlorine gas into the flour after it was milled.

Chlorine gas, a deadly poison if inhaled, not only bleaches the flour but also reacts with other molecules in the flour. Many potentially toxic chlorinated lipid compounds are formed from this chlorine gas, such as dichlorostearic acid.

Chlorine also destroys major portions of Vitamin E as well as an important amino acid in the bread protein, methionine (which is classified as "essential" for human nutrition).

Other chemical oxidizers are added to bleach and "mature" the flour, such as nitrogen dioxide, benzoyl peroxide, potassium bromate, potassium iodate, and azocarbonamide. Are they dangerous? *Well, Germany banned all such oxidizers back in 1958, 24 years ago!*

For softness and that white-bread texture, mono- and diglycerides are added to the bread dough at the rate of about 1/4 pound per year per person consumption. The effect is to make the bread more "plastic" or squeezable—nobody knows the effects on those that eat such additives.

What has happened since World War II is that man, for 5000 years previously, *mechanically* altered the wheat molecule by pounding and grinding. Now he has been chemically manipulating and reorganizing the wheat molecules. These chemical alterations in our food must have serious and long-time effects on those that eat such foods.

Out of the 100 pounds or so of commercial bread eaten each year by the average person, he also eats besides the refined flour such things as 2 pounds of salt, 3 pounds of sugar, 2 pounds of skim milk powder, 2 pounds of yeast, 1 pound of "enzyme-activator," 1/2 pound of sulfate, chloride and bromate chemicals, and 1/4 pound of other food additives. When all of these chemicals and nonfoods are eaten together, a *multi-toxic* effect occurs that has never been thoroughly studied by scientists.

### **1.10 Are Homemade Breads Any Better?**

By now, most health-conscious people know that commercial breads (even 'whole-wheat' and organic ones) are health-destroying foods. So, these people often make their own bread. Does this make bread a "good" food?

Actually, no. Unless these people *freshly* grind their flour from organic, whole grains immediately before they make bread, they're still going to be using a substandard, toxic, and probably rancid flour.

Even if they use freshly ground flour, they still must add such things as salt, a sweetener, maybe some yeast, possibly eggs, milk, etc., and the product has been transformed into a mishmash of indigestible food combinations. All bread is usually cooked as well, which also adds to its toxicity.

Some people who feel that they must have bread have managed to compromise by making an uncooked product using only sprouted grains. Used in moderation, this is a marginally acceptable food. Due to its starchy and indigestible nature, however, such foods are not needed nor recommended for an optimum diet. If bread is ever included in the diet, it should be eaten as a starchy food and combined with leafy and nonstarchy vegetables.

The best way to use grain foods is not in bread, crackers, pasta, or whatever, but in their raw sprouted state. However, grains are only eaten when such foods as fruits, vegetables, sprouts, nuts or seeds are in short supply or not available.

### **1.11 The First "Health" Food**

In the late 1880s, Dr. John Harvey Kellogg ran a sanitarium for vegetarian Adventists. Searching for a healthy meat substitute for his patients, Dr. Kellogg invented "Corn Flakes" in 1895.

One of Kellogg's patients, C.W. Post, was experimenting on himself to devise a "food cure." He came up with "Grape-Nuts," and the breakfast cereal industry was born.

Within five years, Post's cereals were making over a million dollars a year, and Kellogg had taken over the town of Battle Creek, Michigan, with his cereal factories. Up in Niagara Falls, Nabisco's Shredded Wheat had arrived on the scene, and the dietetic character of the nation was being slowly molded.

These three cereal companies were almost solely responsible for making refined cereals a major part of the American diet. The cereals were originally promoted for their supposed health benefits, and industrialized America was ready for its first convenience foods. Breakfast cereals had become the first commercial "health" food.

## 1.12 How Healthy Are They?

Television commercials tell us that if we eat one cup of this or that specially fortified cereal, we'll get 100% of almost all our vitamin and mineral requirements. They don't tell you that these vitamins and minerals are *inorganic* fillers and additives which have been laced through a sugar-coated product that is destructive to our health and well-being.

Nor do they tell that the reason they add those vitamins, etc. is because all the original nutrients in the grain have been heated, rolled, puffed, squeezed and sugared out of existence. The vitamins and minerals are added so the manufacturers can justify the prices they charge for a product that is Only slightly more nutritious than the box it comes in.

And the cereal manufacturers really blow their own horn about these miniscule amounts of nutrition by the advertising on the boxes and on television. If your chief source of nutritional information about breakfast cereals has been the charts and panels on the sides of cereal boxes, then the following facts may open your eyes to one of the biggest food frauds of the twentieth century.

## 1.13 It Used To Be A Grain Of Corn

What is a corn flake? How is it made?

First, the kernels of corn are soaked in lye. Lye is a caustic, corrosive substance that will burn skin off your body. It's used in making rayon, soaps, and—breakfast cereals.

After the soaking, the kernels are blasted by live steam. Then a flavoring syrup full of mostly white sugar is poured over the soaked and steamed corn.

Next, the kernels are dried until they're hard. Then they're run through huge rollers that press down with 75 tons of pressure to flatten them out. Now they're ready to be toasted, heated and flaked one more time. Then they get their last dosing of preservatives, additives and chemicals and are packaged up in a brightly colored box with a picture of an athlete, animal, or cartoon character on the front.

Originally you had a grain of corn, fairly rich in protein, phosphorus, Vitamin A, and the three major B vitamins. Now you've got a sugar-frosted flake that has no original vitamins, few minerals, and an altered protein that is harmful to the body. What's more, you're probably paying five to ten times as much for this processed, denatured food than you would if you had just bought the original whole grain.

## 1.14 Why Do People Eat Prepared Cereals?

The American public has been completely sold on the healthfulness of eating an early morning breakfast and on eating cold cereals as a convenient, nutritious breakfast food. Consider what Richard Carter, author of "The Unappetizing Truth About Dry Cereals," says about cereal consumers.

"As they put this mixture into their mouths, many of the feeders actually glow with a sense of well-being. Decades of tradition and millions and millions of dollars in advertising have trained them to regard their ready-to-eat breakfast cereals as the last word in morning nourishment. Any suspicion that the stuff is nutritionally inferior to other breakfast foods, like fresh fruits, is bound to be dispelled by the sales literature printed on the brightly-colored boxes."

So people eat breakfast cereals because: 1) they feel that they should eat something every day as soon as they get up, according to conventional nutrition; 2) cereals require a minimum of preparation and are easy to eat; 3) people believe that the cereals themselves furnish "minimum daily requirements" due to the added vitamins and minerals.

In response: 1) Most people would be better off if they did not eat first thing in the morning; this is the body's time to clean house and it is not ready to digest food. Greater health could result if people would adopt a sensible "No-Breakfast" plan, and ate more nutritious foods later in the day. 2) Fruits are far

superior to cereals as a nutritious breakfast food, and they are the ultimate convenience food—no milk, no bowls, no preparation or clean-up whatsoever. 3) Added nutrients to food ("fortified" foods) are not utilized by the body like the naturally occurring organic elements. They in no way replace or serve the same functions as do vitamins, minerals, and co-existing nutrients in natural foods.

### **1.15 The Real Harm of Breakfast Cereals**

For many people, breakfast is the same almost every day of the week. Most people eat breakfast out of habit. They rarely make a conscious decision as to what to eat first thing in the morning, and so if they eat cereals they do so almost every day.

The cereal habit is also hard to break not only because of mental habits, but because the high-sugar content of the cereals can create a physical, addictive habit as well. The most popular cereals are 25% to 50% *refined white sugar*, which makes them sweeter than chocolate candy. Granolas, or health food cereals, are hardly better; with their high honey and maple syrup content, they, too, may be 20% to 30% concentrated sugars.

Eating such heavily sweetened breakfast cereals first thing in the morning plays havoc with the blood-sugar levels, and creates the conditions for a life-long sugar addiction.

### **1.16 And It's Indigestible Too...**

Not only is breakfast cereal an abysmal food by itself, it's usually eaten with such foods as milk and fresh fruits so that it becomes virtually indigestible.

Besides being a totally unsuitable food, pasteurized milk that is poured over cereal combines very poorly with any other food. Milk is a protein with a high fat content. Cereals are refined starches and sugars. Putting those types of foods together in the stomach is a sure invitation to acid indigestion.

Fresh fruits are generally acidic or sub-acidic in nature. Mixing them with starchy cereals creates a fermenting environment that negates any health benefits of the fruit to begin with. Better to just eat the fruit and forget the cereal.

If anything is to be eaten early in the day, it should be easily digested, high-fluid foods such as fresh fruits. Refined starches clog the body and their waste products create a feeling of heavy lassitude that lasts throughout the day.

### **1.17 Are Grains Good Food At All?**

So far, we have discussed mostly refined grain products, such as flours, breads, and cereals. There is little disagreement among health-minded people that such refined grain products are harmful and should be completely eliminated from the diet. But what about *whole* grains? Are unrefined grains, like rice, corn, and wheat, eaten in their whole state beneficial and optimum foods?

If we strictly apply the test of an optimum food which is that it be palatable and nourishing in its raw state, then grains fail. Raw grains, except when they are in their young milky stage or sprouted, are virtually indigestible and high in phytic acid which tends to bind calcium, iron, and zinc and make them unavailable to your body.

Grains are also unbalanced in potassium and sodium. Grain-eaters often try to balance the sodium-deficiency of grains by adding salt which is an inorganic poison. In general, grains are deficient in the alkaline minerals, too rich in nitrogen and phosphoric acid, and tend to *acidify* the system.

The starches in grains are hard to digest (about ten times more difficult than potato starches) and are prone to fermentation.

Grains, according to Otto Carque author of *Rational Diet*, are incapable of building strong bones and

teeth. Man cannot live exclusively on grains for any length of time and maintain the best of health. If grains are eaten, they must be accompanied by green leafy vegetables to supply needed alkaline elements.

Grains contain the largest amount of starches of all foods. Humans are not naturally starch-eaters. We only have one starch-digesting enzyme, and that is found in the saliva. Starches are difficult foods to digest, and we would do better to look to other foods, such as fruits, vegetables and nuts for our energy and carbohydrate needs. *Starches are not a necessary part of the diet.* There is not a particle of starch in the entire constitution of your body.

Grains are a relatively new food in the human dietary—hardly 10,000 years old—and refined grain products have really only been around for 200 years in their present form. Man prospered very well before the advent of grain foods, so they cannot be defended as an essential part of the diet.

In fairness, it must be noted that grains, because of their storage capabilities and other considerations, have formed a major part of the world's diet for many different populations. Grains, in their whole form, are not being degraded as an unsuitable food for man—but they are not optimum foods. As long as fresh fruits, vegetables, nuts and seeds are available, grains can be eliminated from the diet forever.

With a reorientation of agriculture from the mono-grain crops to the more productive tree crops (fruits and nuts), the world's population could be better nourished in a more ecological fashion.

## 1.18 Other Refined Grain Products

Although most grain consumed in America is in the form of breads or cereals, other products are used in large amounts. *White rice* is generally polished whole rice. This polishing strips away many of the B vitamins and some of the protein—about the same thing that happens to refined wheat. White rice is a nutritionally unbalanced food and should never be eaten.

Corn meal may also be degermed (refined) and then subsequently "enriched" just like the white flour from wheat grain. Eating such refined corn meal was one of the causes of *pellagra* in the South, or so it was speculated many years ago. Refined corn also causes a B vitamin depletion in the body, the same as refined wheat flour.

*Pasta* such as macaroni, spaghetti, noodles, etc. are usually made from *semolina* which is a refined white flour made from wheat. It, too, is like eating "white bread."

Of course, all such pastries like cookies, cakes, pies, doughnuts, and other such desserts are made with both refined flour and refined sugar and are "double-trouble."

For improved health, all such flour products, whether made from white flour or whole-wheat flour or whatever, should be eliminated from the diet. Once a grain is made into flour, rapid deterioration of the food starts, regardless of the amount of any additional refining or processing.

[Home](#) > [Lesson 31 - Refined And Processed Foods Are Hazardous To Your Health](#) > 2. Questions & Answers

## 2. Questions & Answers

**Are you telling me that I should never eat another slice of bread? I always eat bread with about every meal. What could be wrong with that?**

Whether or not you eat bread, or any food, is something only you can decide. We only try to

present facts upon which you can base a rational decision. Most people eat foods without knowing the true nature of the food itself. Bread is a good example of this. Bread has been on the table for hundreds of years. It is a familiar food, so much that we frequently confuse its familiarity with its necessity.

Most bread eaten today bears no resemblance to the bread of the past. You're eating a slice of fortified chemicals in a plastic, pasty form. This includes most whole wheat and other "organic" breads sold today as well as white bread.

Even if you can get "good" bread or make your own, bread is not a recommended food. For one thing, as you yourself said, people tend to eat it with every meal and all sorts of foods. Bread is a very starchy food, and if it is eaten at all, it should only be consumed with leafy green vegetables and little else.

There are better ways to eat grains, if you want them, instead of in bread or any flour products. Once you grind grains into flour, you've begun the total destruction of a food that was not optimum to begin with.

Of course, we're not "telling" you to do any one thing or the other, nor are we saying something is "wrong" or "right." We only wish to present the facts, as we currently understand them, about grains and grain products. You are to evaluate that information, and make your own decision as you see it for better health.

**Most people in the world make grains a major part of their diet. Japan has rice, Mexico has corn, Europe uses wheat. Are you saying all these people are wrong?**

Again, it is not a matter of right or wrong. When foods are in short supply, such as fresh fruits and vegetables, grains have served as a substitute for optimum nutrition. We should not allow a substitute to become a standard simply because it is widely used. Then, too, remember a distinction is made between whole grains and refined grains. If all these people had eaten refined grain products for all these years, I doubt if there would be many people left in the world today.

In America, Argentina, and New Zealand, for example, meat-eating is more widespread than grain eating. Do sheer numbers make a practice advisable or not? We're not playing a numbers game with nutrition—good health and diets are not dictated by majority rule.

**My children just won't eat anything except cereals for breakfast. When I try to give them something else to eat, they become cranky and cry and refuse to eat it. What should I do?**

There have been very few incidents where children immediately drop dead when not fed breakfast. If your children refuse to eat a healthy breakfast (usually fresh fruits), then serve them nothing at all. Better to go without food than to eat the sugared, chemical mess that is disguised as food in cereal boxes.

The fact that the children complain, whine and cry should indicate to you that they have become "addicted" to the sugar in the cereals. When their blood-sugar renormalizes and they kick the cereal habit, they will welcome wholesome foods such as bananas or grapes or melon for breakfast.

**What's worse—white flour or white sugar?**

An interesting question. I hope you're not considering eating the less harmful of the two!

Actually, you often find these two items used together in foods—like in cakes, pies, doughnuts, cookies, pastries, and so on. The sugar rots your teeth and destroys your nerves while the white flour constipates you and gives you an acid stomach. I know of few white foods that exist in nature. White sugar, white flour, salt, cocaine, heroin, refined fructose—all the white powdery, grainy "foods" are drugs and poisons. Mushrooms I suppose are one of the few natural "white" foods—but even these are often poisonous and substandard foods for humans. So if your food doesn't have attractive colors (like yellow, red, green, etc.), you should probably avoid it (this would of course mean not eating black, grey and browned meats).

[Home](#) > [Lesson 31 - Refined And Processed Foods Are Hazardous To Your Health](#) > Article #1: Pure Starch Factors By Thomas E. Scown

### **Article #1: Pure Starch Factors By Thomas E. Scown**

There are a number of "foods" which may be classified as pure starch: bleached flour, degerminated corn meal, corn-starch, white rice, "instant mashed potato" powder, dextrose, etc. When these refined starches are introduced into the body, a high percentage of the starch is quickly broken down into simple sugars. The sudden flood of sugar into the bloodstream stimulates the pancreas to produce an excess of insulin. The insulin rapidly burns the sugar, causing the blood-sugar level to drop far below normal. A prolonged state of low blood-sugar has been known to cause brain damage. Even short periods of low blood-sugar may cause trembling of the hands, temporary loss of visual control, alternating spasm and weakness in the muscles over the whole body, and many other effects.

Unfortunately, most people in the "highly advanced" nations are eating an ever-increasing proportion of foods composed primarily of pure-starch, sugar, salt, and plastic fat.

### **High energy potential**

Many people have read of explosions in coal mines (from coal dust), but how many people have heard about explosions in flour mills? Many mill workers have discovered, the hard way, that one pound of white flour (suspended in air) has more explosive potential than one pound of T.N.T. The ignition factor may be a spark from the brushes of an electric motor.

Over the past one hundred years, dozens of flour mills have been blasted to bits, each of them destroyed by less white flour than the average American eats in one year.

The explosive potential of refined white flour indicates its chemical nature. It is a highly reactive chemical mixture when certain factors are added.

The human body has hundreds of chemicals involved in the act of living. Add to this the highly reactive chemical mix commonly called "white flour" and all manner of physical derangements will occur.

### **Artificial Flavorings**

Such as used in icings and fillings for doughnuts, cookies, and cakes.

One flavoring product, labeled *Imitation Strawberry*, listed the following ingredients: Vanillin and other aldehydes, ethyl butyrate and other esters, oil lemon and other essential oils, Butyric and other organic acids, benzodi-hydropyrone, ionone and other ketones, alcohol, propylene glycol, water, artificial color

and 0.1% benzoate of soda.

This chemical concoction is only the flavoring; there is also additional artificial coloring added to the "food."

A point to ponder: Most of these chemicals are made from coal and crude oil. Remember those news spots on television showing all the sea birds, fish and clams which died from ingesting crude oil from tanker spills?

[Home](#) > [Lesson 31 - Refined And Processed Foods Are Hazardous To Your Health](#) > Article #2: Cereals, Grain, Flour

## **Article #2: Cereals, Grain, Flour**

The basic grains used worldwide are wheat, rice, oats, rye, barley, millet, corn. Grains have been the mainstay of whole populations—particularly rice and wheat. The reason for this universal reliance on grains is the ease of cultivation, the short growing and maturing time and the facility of bulk transportation and storage for long periods of time. Grains used today are generally refined products and constituted almost exclusively of starch.

Cereals and grains, in their whole grain dry state, may contribute beneficially to the diet of man. But it must be pointed out that even in their most complete state they are not a necessary food and are quite inferior to true foods for man—vegetables, fruits and nuts.

Refined flour (made from any of the grains) is a devitalized substance not suited for human consumption. In fact, it contributes to the general degeneration of those who consume it. It has become one of the principal items in the diets of modern men in the form of bread, rolls, cakes, cookies, spaghetti, etc. There is no way that such devitalized flour can be 'revitalized,' 'enriched' or in any way improved by the addition of elements needed in nutrition (vitamins, minerals, etc.). It remains a nonfood, pure starch, of the worst order. Breads and pastries as the "staple" of the diets of modern life are the source of much of the physical distress of man.

Cereals in the form to be soaked and cooked and the roasted flaked cereals in common use today are produced from denatured grains and are a true curse to mankind. These devitalized substances, further adulterated with sugar, salt, preservatives, chemicals, coloring and artificial flavoring, are contributing to the rapid proliferation of disease among modern man.

Cereals and cereal products (starches) are among the most difficult substances to digest when eaten alone. When eaten in combination with protein, the results are disastrous, resulting in extreme fermentation, gas, acids and intoxication.

Cereal starches require about 10 times longer to digest than do potato starches—the longer the digestion period, the more the fermentation.

Cereals, grains and all concentrated starch foods are unwholesome for human consumption and should be carefully omitted from any health-promoting diet.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > 1. The Principle Hygienic Concern Is Optimal Health

### 1. The Principle Hygienic Concern Is Optimal Health

In the study of Natural Hygiene, we are concerned primarily with lifestyle and eating patterns which will result in optimal health and longevity. Much has been written about the "Vegetarian Alternative," and the many reasons for avoiding the consumption of meat—all flesh foods: beef, veal, lamb, poultry and fish. Such reasons run the gamut from compassion and humanitarianism, ethics and morality, religion, aesthetics, ecology, conservation of resources (land, water, energy, food), economics—and better health.

In this lesson, we will be concerned with the anatomical, physiological, pathological and nutritional reasons for eliminating flesh foods from the human diet, and why optimal health is not possible on a

meat-based diet. We will discuss the health problems that can be caused by the consumption of flesh foods, and the vibrant health that can be attained (or regained) by adherence to Hygienic principles of living and eating—without flesh foods.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > 2. The Best Fuel For The Human Body

## **2. The Best Fuel For The Human Body**

The human body can be maintained on a conglomerate assortment of foods, or our race would have long since vanished. A gasoline engine can operate on kerosene, but it will clog up, parts will wear out sooner, and its serviceable life will be greatly reduced.

The human body will also work best and last longest when fed the fuel intended for man and on which he will best survive: raw fruits, raw vegetables, raw unsalted nuts and seeds, and sprouted legumes and grains. The biological equipment of humans is such that the body is much more capable of obtaining complete and optimal nutrition, without threat or stress, from plant foods.

### **2.1 Plants Are The Source Of Food Elements**

It is a fact that all nutritive material is formed in the plant kingdom—animals have the power to appropriate but never to form or create food elements. Plants can synthesize amino acids from air, earth and water, but animals—including humans—are dependent on plant protein, either directly by eating the plant, or indirectly by eating an animal which has eaten the plant.

A plant-eater utilizes one-tenth of the energy stored in his food—a meat-eater utilizes from meat only one-hundredth of the energy that was originally stored in the primary source, the plants. (Robert H. Dunn, M.D., M.P.H., Director of Preventive Medicine, Washington Adventist Hospital, *Introduction to Meat on the Menu: Who Needs It?* by Raymond H. Woolsey, published 1974.)

Out of the amino acids found in plant and/or animal tissues used as food, the living organism synthesizes the numerous proteins needed by the cells and tissues of its own body. There are no amino acids in flesh that the animal did not derive from the plant, and that man cannot also derive from the plant.

Those who eat animals get only the nutritional elements which the animals have obtained from vegetation, and are of necessity deteriorated with the impurities, and putrescence invariably present in their blood and tissues.

When you eat foods from the plant kingdom, you receive the amino acids in ideal combinations with other substances which are essential to the full utilization of protein: carbohydrates, minerals, vitamins, enzymes, hormones—in addition to chlorophyll, which only plants can supply.

The best sources of concentrated protein for many are raw, unsalted nuts and seeds. In the raw state, all enzymes are intact and the amino acids are wholesomely alive and unchanged. They contain all the vitamins, minerals, trace elements, carbohydrates, hormones—and the life force necessary for the human organism to produce tissue and other body constituents of the highest quality.

### 3. Flesh Foods Cause Degenerative Disease

The habitual and frequent use of large amounts of flesh foods in the diet is actually one of the causes of degenerative disease in a substantial percentage of the population. The decrease in, or elimination of, flesh foods from the diet is one of the important steps toward optimal health.

Man's anatomy and physiology are poorly adapted to the processing of meat, and it cannot be done without some putrefaction (in addition to the putrefaction already present in the meat at the time it is consumed). The result is toxemia, which is the starting point of degenerative diseases like gout, arthritis, heart disease, hardening of the arteries, stroke, osteoporosis, cancer, etc.

#### 3.1 Anatomical and Physiological Basis for Rejecting Flesh Foods

There is a sound anatomical and physiological basis for the recommendation against the consumption of flesh foods. The human anatomy and digestive system are totally dissimilar from those of carnivores, which have sharp claws and teeth for killing and tearing. Carnivorous animals have short intestinal canals, and strong secretions of hydrochloric acid, so as to quickly digest and expel the waste products of the flesh they consume, before putrefaction can occur.

Flesh-eating animals also have the enzyme uricase, which breaks down uric acid into a harmless substance called allantoin; man does not possess this enzyme. Vegetable proteins, including nuts and seeds, contain enough carbohydrates to render this enzyme unnecessary.

The carbohydrate content of nuts also prevents a process called de-amination. Because the carbohydrate content of flesh foods is negligible, conventional nutritionists advocate eating protein with a carbohydrate since it is thought that the presence of carbohydrates is necessary for the digestion of protein and, when none are present, the liver will break down some of the amino acids and convert them to carbohydrates. If this is true (and the experiments have not been conclusive), then it is obvious that the nuts supplied to us by Nature come completely packaged along with their digestive requirements, while flesh foods do not.

Lesson 18 of this course includes a preliminary discussion of this subject and contains an interesting chart, "Classification of Animals," which is an effective demonstration of the fact that man is not a carnivore.

One of the comparisons that is made in this chart is the length of the alimentary canals, which are three times the length of the body in the carnivora, ten times the length of the body in the omnivora, and twelve times the length of the body in the anthropoid apes and in humans. These figures, of course, are approximate. Gray's anatomy gives the length of the human alimentary canal as approximately thirty feet.

Hereward Carrington, in *The Natural Food of Man*, says that some have made the blunder of calling the proportionate length of the human alimentary canal one to six instead of one to twelve, by doubling the height through measuring humans while they are standing erect. He says, "This measurement is evidently wrong, for it includes the length of the lower extremities, or hind legs, whereas, in other animals, the measurement is made from the tip of the nose to the end of the backbone."

The human digestive tract is about four times as long as in the carnivorous animal. The gastric juices of humans have less active antiseptic and germicidal properties. The intestine of the carnivore is short and smooth, to dissolve food rapidly and pass it out of the system. The human digestive tract is corrugated or sacculated, for the express purpose of retaining the food as long as possible in the intestine until all possible nutriment has been extracted from it.

These (and the other anatomical and physiological characteristics of the human digestive system) are the

worst possible conditions for the processing of flesh foods. The excessive secretion of bile (necessitated for the digestion of flesh foods) may result in the premature breakdown of the liver, and the large quantities of uric acid created by a flesh diet may have disastrous effects on the kidneys. Dr. Robert Perk says that the excess of uric acid "causes contraction of the minute blood vessels, resulting in high arterial tension and often the blocking of the blood vessels by the uric acid. This results in serious interference with the circulation and blood supply to the tissues and throws great strain on the vital organs, especially the heart and kidneys." (*Scientific Vegetarianism*, Szekely, p. 44.)

### **3.2 Morbid Results of Eating Flesh Foods**

Meat is the most putrefactive of all foods. Flesh, when eaten by humans, tends to undergo a process of decay in the stomach, causing a poisoning of the blood. Putrefaction in meat eaters is evidenced by bad breath, heartburn, eructations, and the foul stool and odorous emissions—absent in vegetarians—and it is probable that the attempts of the body to eliminate these wastes has a profound influence on the shortening of man's life span.

If the body fluid that bathes our cell's is overloaded with waste, causing an excessive secretion of bile—fatigue, weakening and aging are the inevitable results. The accumulation of toxic substances in the body causes the deterioration of the intestinal flora, and the blood vessels gradually lose their natural elasticity—their walls become hardened and thickened. Irreversible damage to the organism proliferates.

### **3.3 Can You Face The Ugly Truth About Meat?**

Meats contain waste products that the animal did not get to eliminate, and toxic hormones and fluids released into the blood stream and tissues at the moment of the death of the terrified animal.

An animal's cellular life continues after death. The cells continue to produce waste materials which are trapped in the blood and decaying tissues. The nitrogenous extracts which are trapped in the animal's muscles are partially responsible for the flavor of the cooked meat.

Humans who eat the livers of the animals are bombarded with an even greater concentration of waste products and toxic substances. The liver, being the filtering organ of the body, is loaded with elements the body cannot use, which are trapped in the liver and remain there. Liver eaters are treated to higher concentrations of mercury and artificial hormones, plus other "goodies" that remain in the animal's disposal system.

Liver increases, even more than muscle meat, the amount of creatine in the urine. Creatinuria (abnormal amounts of creatine in the urine) is involved in endocrine (glandular) disorders.

Meat not only harbors the bacteria infecting the living animal, but it may also carry molds, spores, yeasts and bacilli picked up during postmortem handling.

A book on meat processing explains that the flesh becomes more tender and palatable by the process of ripening, hanging and maturing (aging). Vic Sussman, in *The Vegetarian Alternative*, pp. 149-150, says, "Few meat eaters would like to hear the words putrefaction, rigor mortis, and rotting applied to their sirloin and pot roast. But flesh is flesh, though the euphemisms ripening, toughening and enzymatic action are kinder to the ear."

Trained government inspectors use sight, smell and touch in a constant battle to protect meat eaters from intentional and accidental abuses. But effective regulation of flesh food is enormously difficult. Sussman says (p. 151) "Even the most conscientious inspectors are forced by circumstances and the pressure of time to let suspect carcasses leave the plant."

Those who eat processed meats also get many of the odds and ends of the animals—eyes, ears, bladders, lips, udders, snouts and parts of the bones and skin. Not even a meat inspector can tell from what part of the body the sausages and frankfurters came—it is all meat tissue, and all legal. (Woolsey, *Meat on the*

*Menu...*, pp. 21-22.)

In his pediatrics textbook, Dr. Emmet L. Holt of New York City says that if two dogs were put on a leash and one fed water and the other beef tea, the dog getting the water would live longer, because beef tea does not contain any nourishment if the fat is skimmed off, but does contain urinary wastes, which poison the dog.

Owen S. Parrette, M.D., in *Why I Don't Eat Meat*, p. 13, says that when he was a medical student, the class was given glass test tubes to be used for growing bacteria that are present in human diseases such as typhoid, staphylococci, and bubonic plague. "The professor had us make up some beef tea, pour a little into each test tube, and place a cotton cork on top. We sterilized the tubes and later inoculated them with these dangerous bacteria. The germs all thrived on the beef tea. It was a perfect medium for them."

Carrington also says (p. 109), "Meat-eating is the more or less direct cause of various diseases." The tapeworm embryos are carried by beef, pork and fish. The deadly trichina parasite is found mainly in pork, but also in fish, fowl and other meats. Trichinosis closely resembles cerebro-spinal meningitis. Tuberculosis has been communicated from cattle, typhoid fever from oysters. Epilepsy has been traced to meat-eating.

Twenty-six diseases, including salmonellosis, staphylococcus and psittacosis, are known to be common to both man and poultry. (*Meat on the Menu...*, Woolsey, p. 27.)

Since little or no progress has been made in eradicating these dangers, the only people who are immune are those who never eat meat. Authorities recognize that the basic problem is with the nature of the product itself. The National Academy of Science reports, "Reluctantly, we are forced to recognize the infeasibility of eradicating salmonellosis at this time." ("An evaluation of the Salmonella Problem," National Academy of Sciences, Washington, D.C., 1969)

The late Dr. John Harvey Kellogg said, when he sat down to his vegetarian meal, "It is nice to eat a meal and not have to worry about what your food may have died from."

### **3.4 Meat-Eating Predisposes to Disease**

In addition to directly causing certain diseases, meat-eating also predisposes the body to disease. In pestilences of any character, meat-eaters are the chief sufferers. Wounds heal far more rapidly in vegetarian soldiers. Carnivores are far more subject to blood poisoning than are vegetarians. Vegetarians survive major operations more frequently than meat-eaters. (Carrington, pp. 111-112).

John A. Scharffenberg, M.D., in *Problems with Meat* says, "Meat is a major factor in the leading causes of death in the United States, and probably in similarly affluent societies. In fact, next to tobacco and alcohol, meat is the greatest single cause of mortality in the United States." He makes this statement on p. 101 of his well-documented book, in summarizing "the formidable and persuasive scientific evidence we now have." He marshals this scientific evidence of the disease potential of meat and the relationship of meat to these specific problems: atherosclerosis, cancer, decrease in longevity or life expectancy, kidney disorders, osteoporosis, salmonellosis, and trichinosis. He quotes an editorial statement in the *Journal of the American Medical Association*: "A vegetarian diet can prevent 97% of our coronary occlusions." (Editor: Diet and Stress in Vascular Disease, *JAMA*, 76:134-35, 1961).

Several more recent, well-organized studies have identified the risk factors of atherosclerosis and heart attacks: a 1970 study by twenty-nine voluntary health agencies, in cooperation with the American Medical Association (these study groups consisted of many of the nation's top scientists); a 1977 study by the Senate Select Committee on Nutrition and Human Needs: a twelve-year Finnish Mental Hospital Study (Effect of cholesterol-lowering diet on mortality from coronary heart disease and other causes, *Lancet* 2:835-38, 1972); and a 1975 study comparing Seventh Day Adventists who had different dietary habits. The Seventh Day Adventist study revealed a 64% vulnerability to coronary heart disease in meat-users, 40% for lacto-ovo-vegetarians, and 23% for total vegetarians. The 1977 study by the Senate

Select Committee on Nutrition and Human Needs reported the significant deleterious influence of the consumption of dietary cholesterol (animal fat) and recommended the increased use of fruits, vegetables and whole grains, and a decrease in the use of foods containing saturated fat (animal fat).

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > 4. Vegetarianism Is Receiving More Attention

#### **4. Vegetarianism Is Receiving More Attention**

A consideration of an article from *Today's Health*, published by the American Medical Association, appeared in the February 1975 *Readers' Digest*. The article states: "Americans are meat eaters by tradition. Yet statistics show that vegetarians in this country are thinner, in better health, with lower blood cholesterol, than their flesh-eating fellow citizens. They may even live longer."

The article mentions studies by Dr. Frederick Stare (!!) of Harvard and Dr. Mervyn Hardinge, Loma Linda, California School of Health, indicating that vegetarians have consistently lower levels of cholesterol. (It is rare indeed that Dr. Stare is ever "caught" criticizing the conventional diet.)

Quoting further from the article: "Meat eaters also may be bothered by poor elimination. Food with a low fiber content, such as meat, moves sluggishly through the digestive tract, making stools dry and hard to pass. Vegetables, by contrast, retain moisture and bind waste bulk for easy passage."

The article cites documentation of the excellent health and longevity enjoyed by the Hunzas of Pakistan and the Otomi Indians of Mexico, confirmed by field investigations of these nonmeat cultures.

Reference is made to the experiences of Denmark and Norway, where the general health of the people improved when vegetarian diets were adopted during World Wars I and II, including a significant reduction in heart disease. "Both nations, however, reverted to meat diets as soon as the crises passed, and subsequent studies showed that the temporary health advantages apparently subsided."

Remember, THIS INFORMATION WAS PUBLISHED IN THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION IN 1975. Since then, vegetarianism and low-fat diets in general have been receiving more attention, and reports are trickling down of medical doctors who are recommending eliminating meat from the diets of arthritis and cancer patients, and even of medical doctors who are acknowledging the health benefits of vegetarianism for themselves and all of their patients.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > 5. The Evidence Is Mounting

#### **5. The Evidence Is Mounting**

Autopsies performed in Korea showed that 75% of American soldiers had hardened arteries, regardless of their age. Korean soldiers, on a simple diet of vegetables, grains, and very little meat, showed essentially no hardening of the arteries.

Worms are found in fish taken in the cold waters of Yellowstone Lake, and even in fish taken twenty miles out into the Gulf of Mexico. Dr. Parrette's *Why I Don't Eat Meat*, published in 1972, says on page 17, "On the desk in front of me is a clipping from a recent *Los Angeles Times* entitled "Disease Causes Halt of Some Trout Imports." The article tells of the California Fish and Game Department turning back six tank cars of rainbow trout fingerling that were shipped into California to stock our lakes and streams,

but were found to be infected with liver cancer ... Rabbits are susceptible to diseases of many kinds. As a lad, I had a friend who used to hunt rabbits and sell them. I often helped him clean them and noticed that nearly all the cottontails were infected with tapeworm."

The rapid rise of leukemia in cattle calls our attention to the fact that blood cancer, or leukemia, is now a major cause of death among children in the United States.

Meat has been implicated in a wide variety of factors and processes known to be associated with cancer, including the following:

1. Chemical carcinogens, added to the meat, or produced by heating.
2. Cancer viruses found in tumors in animals, transmittable to humans.
3. Lessened host resistance to invasive disease.
4. Lack of fiber in meat, increasing transit time through the colon. Adequate fiber is also necessary to help remove bile acids from the gastrointestinal tract. (Colon cancer patients tend to produce more bile acids than other people.)
5. Rapid maturation, early menstruation, higher rates of breast cancer.
6. High-fat diet is also associated with breast cancer.
7. High Prolactin levels—Prolactin is a pituitary hormone promoting milk formation and lactation. A high-fat diet increases the prolactin-estrogen ratio, which then enhances mammary tumor growth. When humans change from a meat to a vegetarian diet, the prolactin surge appears to be reduced to almost one-half. A diet high in fat, meat and milk (high in cholesterol) tends to increase the incidence of breast cancer. (Dr. Scharffenberg, *Problems with Meat*.)

It has been demonstrated that cancer can be transmitted from one (animal or human) species to another.

When one considers the evidence of the cancer-causing potential of meat, it seems incredible that it is ignored by so many intelligent people. Malignant tumors are found in animals. Many years ago I saw a tremendous tumor on the "innards" of a chicken that had been sold at the City Market in Indianapolis. I witnessed the noisy altercation between the indignant customer who was returning the chicken and the proprietor of the stand. An exchange was made, and the returned chicken was dipped in water and returned to the sales counter.

In addition to cancerous tumors in fowl, there is a carrier form which is impossible to detect except by painstaking laboratory experiments. "The conclusions drawn must consider the possibility that all chickens show the basic microscopic lesions of lymphomatosis." (Dr. Eugene F. Oakberg, *Poultry Science*, May, 1950, p. 434)

Colon cancer is acknowledged to be the predominant type of cancer in the United States and the second leading cause of cancer mortality. An article in the Wall Street Journal several years ago tells about a study of colon cancer by Dr. William Haenzel, Dr. John W. Berg and others at the National Cancer Institute, as a result of which Dr. Berg said, "There is now substantial evidence that beef is a key factor in determining bowel cancer incidence."

Scientists have reported evidence that two characteristics of meat-based diets are specific influences in colon cancer:

1. Fecal transit time; a low-fiber diet allows carcinogens to be concentrated and held in contact with the bowel mucosa for long periods, while a high residue diet (a vegetarian diet) produces more rapid passage of body waste.
2. Influence of the diet on the amount of carcinogens produced by the body. It has been found that meat fat tends toward production of carcinogens in the intestine.

Dr. Ernest L. Wynder, president of the American Health Foundation, and a long-time cancer researcher, reported long ago that the results of his studies had convinced him of the cancer hazards of diets high in animal fats. On March 31, 1982, Dr. Wynder, now renowned as the health detective who first linked smoking and cancer a generation ago, reiterated his findings. He said that a low animal fat, high fiber,

fresh fruit and vegetable diet helps fight both cancer and heart disease. He said that the American Heart Association and the National Heart, Lung and Blood Institute also recommend such a diet.

Sussman (*The Vegetarian Alternative*, p. 61) gives documented reports about experiments with an anti-cancer enzyme, which can be produced by the liver, depending on the components of the diet. Dr. Leo Wattenberg of the University of Minnesota School of Medicine isolated the dietary elements that increased ability to produce this enzyme. The agents (called indoles) that induced formation of this enzyme were found in alfalfa, Brussels sprouts, cabbage, celery, turnips, broccoli and cauliflower. Citrus fruits also contain similar enzyme-inducing agents (flavones) and beans and seeds yield a type of plant protein (lectins) that also has demonstrated cancer-resisting effects.

Dr. Anthony B. Miller, director of the National Cancer Institute of Canada, said: "Evidence suggests that certain foods, particularly high intake of dietary fat, are associated with increased risk of colorectal, pancreatic, breast, endometrial, ovarian, prostate and possibly renal cancer." He also recommends increased consumption of fresh fruits and vegetables.

Although these doctors aren't specifically advocating totally vegetarian diets, it is interesting to note that more and more "conventional" professional people are warning against high consumption of animal fat, and recommending increased use of fresh produce.

Hygienists, of course, prefer not to use any part of the animal as food, and find it difficult to understand how so many people can ignore the overwhelming evidence against the use of flesh in the diet.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Modern Methods Accentuate Risks

## **6. Modern Methods Accentuate Risks**

Most of the deleterious influences of meat-eating which have been discussed thus far apply to any flesh foods, even those which are raised the "old-fashioned" way, without chemicals or hormones. The "modern" methods of producing and marketing flesh foods, and fish taken from polluted waters, increase the risks astronomically.

Those who eat processed meats are not only treated to sodium nitrate and sodium nitrite (which, together, form cancer-causing nitrosamines in the body), they also get sodium sulphite. Sodium nitrate and sodium nitrite are used as preservatives to retard the putrefaction process in processed meats (frankfurters, salami, bologna, sausage, etc.) The food can still spoil, but it is not as obvious.

*Consumer Reports*, February 1972, p. 76, reported that, after studying samples from thirty-two brands of frankfurters bought in supermarkets throughout the United States, researchers stated: "Food experts generally agree that putrefaction has set in when a frankfurter's total bacteria count has reached ten million per gram. With that as a yardstick, more than forty per cent of the samples we analyzed had begun to spoil. One sample tested out at 140 million per gram."

Dr. Charles C. Edwards, Commissioner of the Food and Drug Administration, testified before a House Subcommittee in March 1971, stating that sodium nitrite is potentially dangerous to small children, can cause deformities in fetuses, can cause serious damage to anemic persons, and is a possible cause of cancer.

Sodium sulphite is used to give meat a fresh, red appearance, even after it has become rancid and turned black. This chemical will change it back to bright red, and will also "miraculously" eliminate the strong odor of putrefaction.

Dr. Michael Jacobson of the Center for Science in the Public Interest says that sodium nitrate and

sodium nitrite in processed meats have caused numerous cases of blood poisoning (methemoglobinemia), many reported in medical journals. He says that meat contains residues of more than a dozen chemicals used to fatten the animals— all of them proven in the laboratory to cause cancer.

The chemicals and hormones are mixed and administered on the farms by stockmen, who often use greater than recommended amounts, and fail to withdraw drugs far enough ahead of slaughter.

Both penicillin and tetracycline are routinely used in poultry and cattle feed. When the FDA moved toward restricting the addition to animal feed of antibiotics that are also used to combat human diseases (because of the consequent growth of antibiotic resistant bacteria), the meat industry was outraged at the proposal.

Most laws relating to "wholesome" meat apply only to their processing. Some local laws apply to monitoring of sanitary conditions in the market. After that, the consumer is at the mercy of the retailer. Labeling, classification, pricing are variable and undependable. "Economical management" by market owners does not always include discarding spoiled meat. Mold can be washed off, or the meat can be recycled by cutting up, grinding, adding spices, or cooking to disguise color, odor and taste.

"Hearings before a Senate Investigating Committee in 1969 revealed that a major, brand-name, nationally famous meat packer on the West Coast accepted unsold meats from retailers and repackaged and recirculated them. Reasons for returning included moldy, sour, discolored, slick and slimy." (Woolsey, "Meat on the Menu..." p. 38).

Charcoal broiled steaks contain an average of nine micrograms of benzopyrene, a cancer-producing agent. The fat dripping into the fire changes the chemical properties of the fat and the benzopyrene goes up in the smoke from the charcoal and coats the steaks.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > 7. Eating Low On The Food Chain

## **7. Eating Low On The Food Chain**

Eating low on the food chain significantly reduces the threat of pesticide residues. Tests in Britain have shown the pesticide residue levels to be highest in meat eaters, lower in lacto-vegetarians, and lowest in total vegetarians.

This is due to the concentrating factor as the contaminant goes through the additional link in the ecological chain, and the animal concentrates the pollutant in its body. The meat eater may eat in a few minutes the pesticides that an animal has accumulated over a lifetime.

A study by the Washington, D.C.-based Environmental Defense Fund revealed that breast milk of vegetarian women contained significantly lower levels of pesticide residues than that of meat-eating women.

Further research by author Nat Altman disclosed that vegetables and nuts contain about 1/7 the pesticide residues of flesh foods; fruits and legumes about 1/8 as much; and grains about 1/24 as much.

## **8. Meat-Based Diet Presents Complex And Grave Nutritional Problems**

Even beyond the grave dangers presented by meat-based diets is the misconception that meat is an ideal nutritional source against which vegetable proteins are measured and found wanting. The fact is that it is much more difficult to have even a reasonably good diet with meat than without it.

### **8.1 "Complete Protein" Status of Meat?**

In the first place, even the much vaunted "complete protein" status of meat is, at best, based on a colossal error (if not a hoax). The complete protein of the animal could exist only if the animal were consumed raw and whole. Meat-eating animals eat the blood, bones, cartilages, liver, etc. of their prey—not just the muscle and fat. They eat it raw—so that they do not lose any of the mineral elements. The muscle meats (most commonly consumed by humans) are grossly inadequate as a protein source.

On the other hand, humans who eat the livers of the animals don't win either. As previously indicated, those who eat liver are exposed to greater concentrations of morbid substances. Even though liver is touted as an optimal source of such substances as iron, Vitamin A and Vitamin B-12, it can hardly be regarded as anything remotely resembling wholesome food.

For years, conventional nutritionists have maintained that complete and optimal nutrition is assured on a diet using animal foods as the primary source of protein, and that a vegetarian diet presents many problems. Dr. Scharffenberg produces well-documented scientific evidence (*Problems with Meat*) indicating that *the truth is exactly the opposite*.

### **8.2 Meat Deficient in Vitamins, Minerals, Fiber and Carbohydrates and Excessively High in Fat and Concentrated Protein**

Meat is one of the main sources of food that provide little fiber—*flesh foods lengthen the average transit time through the gastrointestinal tract from thirty hours to seventy-seven hours*.

Colon cancer patients produce more than normal amounts of bile acids which enhance cancer growth. A more rapid transit time through the digestive tract reduces exposure time to these acids.

Meat contains virtually no carbohydrates and is excessively high in fat and concentrated protein.

Dr. Bircher-Benner, the great Swiss physician, said, "Meat does not give strength. Its composition is one-sided, lacking certain minerals and vitamins, and it introduces too much fat and protein into the system, disturbing the balance of nutrition and giving rise to intestinal putrefaction."

### **8.3 Meat is Highly Stimulating and Innutritious**

Hereward Carrington, *The Natural Food of Man*, p. 114, says, "In the first place it must be pointed out and insisted upon that meat is a highly *stimulating* article of food, and for that reason, innutritious. Stimulation and nutrition invariably exist in inverse ratio—the more the one, the less the other, and vice versa. The very fact, then, that meat is a stimulant, as it is now universally conceded to be, shows us that it is more or less an innutritious article of diet, and that the supposed "strength" we receive from the meat is due entirely to the stimulating effects upon the system of the various poisons, or toxic substances, introduced into the system, together with the meat. It is for this reason that those who leave off meat and become vegetarians experience a feeling of lassitude and weakness for the first few days—they lack the stimulation formerly supplied, and now notice the reaction which invariably follows such stimulation. This feeling of weakness, or "all-goneness," is therefore to be expected, and is in no way a proof that the diet is weakening the patient. Let him persist in his reformed manner of living for some

time, and he will find that this reaction wears off, and that a general and continued feeling of energy and well-being follow."

## **8.4 Results of High Protein Diets**

### **Organism Subjected to Toxic Byproducts**

Protein is the most complex of all food elements, and its utilization is the most complicated. People with impaired digestions will find it preferable to ingest a lesser quantity of concentrated protein, which they are capable of utilizing, rather than a greater quantity, which not only cannot be processed efficiently, but which may poison the body. When protein is eaten in greater amounts than the body is capable of utilizing, the organism is subjected to the toxic byproducts of protein metabolism, which it has been unable to eliminate—and the inevitable result is degenerative disease.

The tremendous amounts of protein frequently recommended—75 to 100 grams daily (or more)—are far in excess of the body's needs, and are the source of much trouble.

The famous nutritionists Dr. Ragnar Berg, Dr. R. Chittenden, Dr. M. Hindehede, Dr. M. Hegsted, Dr. William C. Rose, and others, have shown in extensive experiments that our actual need for protein is somewhere around thirty grams a day, or even less. Many leading contemporary scientists and nutritionists in Europe, such as Dr. Ralph Bircher, Dr. Bircher-Benner, Dr. Otto Buchinger, Jr., Dr. H. Karstrom, Prof. H.A. Schweigart, Dr. Karl-Otto Aly, and many others, are in full agreement with the findings of Drs. Berg, Chittenden, Rose, et al, and are recommending a low protein diet as the diet most conducive to good health.

### **High Incidence of Degenerative Diseases**

The Seventh-Day Adventists and The Church of Jesus Christ of Latter Day Saints, who advocate a low animal-protein diet, have fifty to seventy per cent lower death rates than those of average Americans. They also are reported to have a much lower incidence of cancer, tuberculosis, coronary diseases, blood and kidney disease, and diseases of the digestive and respiratory organs.

### **Negative Lime Balance (Calcium Transfer)**

Bone calcium is at dangerously low levels in those using meat as compared to vegetarians, especially in people over fifty. A high-protein diet (especially meat protein) increases the urinary excretion of calcium. Thus vegetarians are less prone to osteoporosis (porous bones).

H. J. Curtis' *Biological Mechanism of Aging* gives documentation of the role of high protein diets, particularly animal protein, in causing osteoporosis. Calcium is transferred from the hard tissues (bones) to the soft tissues (arteries, skin, joints, internal organs and eyes). The transfer of calcium to the soft tissues results in catastrophic fractures, hardening of the arteries, wrinkling of skin, arthritis, the formation of stones, cataracts, high blood pressure, degeneration of internal organs, loss of hearing, senility and cancer.

A study of elderly female vegetarians at Michigan State University showed they lost less bone to osteoporosis than a group of the same age that ate meat.

Researchers at the University of Wisconsin found that when the protein intake of young men was raised to 140 grams per day, they all proceeded to lose bone calcium, even though they took liberal amounts of calcium and magnesium supplements and protein extracts which contained no fat and little phosphorus—the supplements didn't help at all.

Young men had strong bone retention with protein intake of around fifty grams per day—only a reduction in protein consumption avoids the threat of osteoporosis.

Athletes who eat much meat are especially susceptible to arthrosis, a degenerative process of the joints. Among twenty conventional-diet professional football players who were observed for eighteen years, 100% incidence of ankle arthrosis and 97.5% of knee arthrosis were found.

A negative lime balance is easily produced by increased protein supply. The eminently important minerals—potassium and magnesium—are known to be deficient in an every day diet rich in meat, eggs, cheese, fat, sugar and grains, but richly present in a full-value vegetarian diet predominating in raw food.

### **Rapid Maturation and Early Death**

Examples are repeatedly cited of robust and apparently healthy individuals who are heavy meat-eaters. Dr. L.H. Newberg of Ann Arbor University found that when he fed large quantities of meat to test animals, they grew bigger and more alert than other animals on a vegetarian diet. But three months later these animals contracted kidney damage and died, while the vegetarian animals lived on healthily and happily. (Wade, C., Vegetarianism, Herald of Health, LXXII, Ap. 1967, p. 14)

Accelerated growth = accelerated maturity, accelerated degeneration and accelerated demise. Rapid growth and short life go together, verified by repeated studies and experiments.

Since rapid maturation occurs as a result of high protein diets, this produces earlier onset of menstruation. Girls who start menstruation before thirteen have a 4.2 times greater incidence of cancer than those who start several years later. In countries with higher meat fat consumption, breast cancer mortality rates increase, and there is a higher incidence of colon and prostate cancer.

It must be emphasized that diet alone is not the single component in cancer and other degenerative diseases, but optimal nutrition does play a fundamental and preventive role, and faulty dietary habits play a causative role.

Kofranyi of the Max Planck Institute in Russia proved that complete nitrogen balance and performance ability could be maintained on 25 grams of protein daily, and Oomen and Hipsley found a population that develops not just full health, but magnificent structure and corresponding physical performance on 15 to 20 grams of protein daily.

## **8.5 The High-Protein Hoax**

Dr. Bircher-Benner describes the method used by the American Research Council's Food and Nutrition Board to agree on a daily requirement for adults of seventy grams, found in their tables.

Sherman, a member of the board, said that evidence pointed toward a much lower amount, somewhere around thirty-five grams. But if the protein requirement had been set so low, there would have been a public outcry. And so, a corresponding "margin of safety" was adopted, and "seventy grams" was published. Because the scientific basis for this was nonexistent, the word "recommendation" was used instead of "requirement." Of course it was publicly interpreted as the requirement, in fact, as the minimum.

"The smallest amount of food able to keep the body in a state of high efficiency is physiologically the most economical, and thus best adapted for the body's needs." This is the Chittenden concept, stated years ago by Russell Henry Chittenden, which applies forcibly to protein. The average American diet contains 45% more protein than even the National Academy of Sciences recommends, and is certainly not "best adapted for the body's needs."

## **8.6 Insoluble Problems of Meat-Based Diets**

Flesh eating is defended almost entirely on the premise that it is a source of superior proteins. The truth is exactly opposite. The pathological effects of encumbering our bodies with the proteins of other animals is Nature's method of vetoing these proteins for human consumption, in order to promote the

stability of the human species and to protect the health of the individual. Dr. Herbert M. Shelton says (*Animal Foods*—booklet) that allergy and anaphylaxis (see definition) are not mysterious; they are due to long-standing poisoning of the body by excess or inappropriate protein foods.

Animal proteins are often not reduced to their constituent amino acids, but are absorbed in more complex form. Absorption by the body of such partially digested proteins poisons the organism, and so-called "allergic symptoms" may be the result—or gout, arthritis, cancer, or any one or more of a host of degenerative diseases.

A meat-eater must also be concerned about digestive problems caused by too little dietary fiber; circulatory problems due to excessive cholesterol deposits from animal fats; loss of bone mass due to inadequate ingestion and retention of calcium; deficiency of vitamins and minerals; and inadequate carbohydrate intake (without increasing calories).

The Senate Committee recommended fifty to sixty per cent of daily calories from carbohydrates, but, actually, it should be more like ninety percent (*provided, of course, that they are natural and not refined*).

It is well-nigh impossible to solve such problems on a meat-based diet.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > 9. A Healthful Diet Without Meat

## **9. A Healthful Diet Without Meat**

Dr. Scharffenberg says, "In contrast, contrary to conventional belief, it is simple for a vegetarian to maintain a healthful diet. There is no worry about cholesterol and little concern about saturated fat. Fiber and carbohydrate are adequate without any special calculation. HOW IRONIC THAT FOR SO LONG IT HAS BEEN THOUGHT THAT IT WAS THE VEGETARIAN WHO HAD DIFFICULTY.

IN LEARNING TO GET ADEQUATE NUTRITION... THE OLD WORRIES ABOUT A VEGETARIAN DIET BEING PROTEIN-DEFICIENT ARE GROUNDLESS AND SHOULD BE LAID TO REST." (Caps mine—author)

The intelligently planned meatless diet has none of the disease problems of flesh foods and provides a dependable source of all the nutrients—including adequate protein.

Complex judgments or computations, such as are necessary in planning a meat-based diet, are obviated. It is extremely difficult for meat eaters to maintain a diet low in saturated fat and cholesterol, high in carbohydrates and fiber, and containing adequate calcium to compensate for the effects of meat in increasing excretion and transfer of calcium.

### **9.1 The Obsolete Amino Acid Theory**

One of the favorite arguments of flesh eaters is that proteins from the plant kingdom are "incomplete," because no one plant food contains all of the twenty-three identifiable amino acids (although the carrot, with twenty-two amino acids, comes quite close). Studies of man's physiology, and the effects of his consumption of foods from the plant kingdom, have shown conclusively that it is not necessary to consume all of the amino acids at one sitting, not even the eight (some references say ten) "essential" amino acids that are not fabricated within the body.

The foods we eat are processed by the body, and the amino acids, vitamins and minerals, and other nutrients are reserved in a pool for later use as needed. When we eat, we replenish the reserves in this pool, to be drawn upon by the cell as required. We do not live upon one protein food, but upon the

protein content of our varied diet, which supplies all of the protein needs of the body. Guyton's "Guidance Textbook of Medical Physiology" is authority for this important information. The book contains five pages showing that amino acids are picked up from the bloodstream and cells of the body.

If you have read *Diet for A Small Planet*, you are familiar with Frances Moore Lappe's assumption that it is necessary to consume all the "essential" amino acids at each meal, and her complicated "solution" to this "problem" for vegetarians by combining certain foods from the plant kingdom to form complete proteins, resulting in some abominable food combinations, which, of course, do not take into account human digestive limitations.

Nowhere in Nature is there any evidence of the necessity for such complicated maneuvering to obtain optimal nutrition. Not only are humans not dependent on the animal kingdom for their nutrition—it is also not necessary to play a numbers game with nutrients or foods at each meal.

## 9.2 The Truth About Amino Acids

New knowledge has completely reversed the old theory, which was based on studies between 1929 and 1950 that used purified amino acids. We eat foods—not purified amino acids. Recurring studies reported in the *Journal of the American Medical Association* and other medical journals (since 1950) show that it is not necessary to feed complete protein at each meal. One such study by E.S. Nasset, reported in *World Review of Nutrition and Dietetics* 14:134-153, 1972, indicated that the body can make up any of the amino acids missing in a particular meal from its own pool of reserves, as long as a variety of foods are included in the diet.

Only gelatin and isolated protein factors are completely devoid of one or more amino acids. "Vegetable protein foods are not lacking totally in any specific amino acid.... the average vegetarian ingests adequate amounts of protein, and the amounts of essential amino acids in the diet not only meet the minimum requirements—they more than twice exceed them." (Scharffenberg, *Problems with Meat.*)

There is also a proliferating availability of additional documentation of the fact that humans and animals fast for lengthy periods, and that, instead of suffering protein deficiency, the end of the fast finds them with restored protein balance. Those individuals who have experienced prolonged fasts (of perhaps fourteen days or longer) invariably have experienced remarkable improvement and hardening of the nails of the fingers and toes. During my twenty-nine day fast in 1967, I marveled at the improvement in my own finger nails, which lengthened and hardened, a new experience for me.

If the body were not capable of storing amino acids, this obviously could not have occurred during a period of abstention from all food. Nor could this have occurred if the protein supply were dependent on continuous and simultaneous external sources of all the essential amino acids.

It is true that protein is not stored in the body in the same sense that excess carbohydrate is stored as glycogen or fat. But the body can compensate for temporary deficiencies by withdrawing what it needs from the pool of materials within the organism—as material is sloughed off intestinal walls, from digestive secretions, and from the autolysis of old cells, fat, etc.

Many foods from the plant kingdom contain so-called "complete" proteins; that is, humans may obtain from them all of the essential amino acids which they cannot synthesize, but from which other amino acids may be synthesized as needed.

The argument that the best source for protein is meat because the analysis of animal protein (amino acids, particularly) is much closer to that of the human body than is plant protein is an excellent argument for cannibalism. If that contention were true, all animals would be best nourished by eating their own species since, obviously, that would be the only source of identical protein and their best source of optimal nutrition. I believe that even the heartiest flesh eaters would find this idea repugnant.

Besides, it must be remembered that no human can use the protein in the form in which it is consumed. It must always be disassembled into its constituents and reassembled or synthesized into the particular

protein required by the cells and tissues of the new host. As previously explained, cooked and coagulated animal protein presents great difficulties in this necessary breakdown of the long chains of amino acids.

### 9.3 Superiority of Uncooked Plant Proteins

All nuts, except the hickory, contain complete proteins. This has been verified by experiments by Cajori, Kellogg and Berg. Sunflower seeds and sesame seeds are in the same category. Peanuts, beans, and a long list of vegetables also contain all the essential amino acids: carrots, Brussels sprouts, cabbage, cauliflower, collard greens, fresh corn, cucumbers, eggplant, kale, okra, peas, potatoes, summer squash, sweet potatoes, and tomatoes. This listing is by no means complete. Most vegetables, of course, contain lesser amounts of amino acids than do concentrated proteins like nuts, seeds and legumes. Soybeans (which may be sprouted and eaten raw) contain all of the essential amino acids—in fact, a higher quantity of all amino acids (weight for weight) than meat or eggs.

Some grains do not contain all of the essential amino acids (as far as has been presently determined). When grains are used together with an abundance of raw green vegetables, whichever amino acids are missing from the grains are well supplied by the green vegetables. But remember that you do not need to concern yourself about securing all of the essential amino acids at one sitting.

An adequate supply of protein in the overall diet is indispensable for normal health and well-being. But such an adequate supply of protein is not dependent on killing animals for food, nor upon using a calculator to add up the amino acids at each meal.

Use a variety of the available Hygienic foods—choosing from fruits, vegetables, nuts, seeds and sprouts—not all at each meal, of course—or even necessarily, every day—but over the course of the weekly diet.

Dr. Hoobler, who did some research at Yale University, demonstrated the superiority of nut protein. It was he who proved conclusively that the protein of nuts not only provides greater nutritive efficiency than that of meat, milk and eggs, but that it is also more effective than a combination of these three animal proteins.

Fruits and vegetables, though containing relatively smaller amounts of protein in their natural state, are excellent sources of supplementary amino acids for complete and optimal nutrition.

The protein in raw nuts and seeds, and in uncooked fruits and vegetables, are readily available to the body, and are therefore said to be of high biological value. During the process of digestion, the long chains of amino acids (the building blocks of protein) are gradually broken up for the body's use in synthesizing its own protein (as any species must do).

It must be reiterated and re-emphasized: when proteins have been cooked or preserved, they are coagulated. Enzyme resistant linkages are formed which resist cleavage, and the amino acids may not be released for body use. In this case, the protein is useless and/or poisonous to the body, becoming soil for bacteria and poisonous decomposition byproducts.

Since the nutrients available from raw food are several hundred per cent greater than those available from food that has been cooked or otherwise processed, and since, obviously, flesh foods are usually not eaten raw by humans, this in itself would be an important reason why first-hand protein foods from the plant kingdom, which may be eaten uncooked, are superior.

Raw food decreases the need for protein in yet another way: the usual conventional diet requires six to eight grams of protein per day for the synthesis of digestive juices. But raw food, with all the enzymes intact, economizes on digestive enzymes.

Nuts are subject to few contaminating influences; they supply everything we can get from flesh foods, in better form, better condition, cleaner, more easily used, and without the risk of eating chemicalized or

diseased flesh foods. And nuts can be eaten without cooking or processing.

Utilization of nuts is best if eaten with uncooked plant foods of high biological value, such as large green salads. Sprouted grains and legumes are excellent supplementary sources of protein of high biological value.

In abnormal conditions, as after a prolonged fast, recovery from a debilitating disease, during lactation or pregnancy, or during weight training, a slightly greater amount of protein may be necessary, *if not in excess of the digestive capabilities of the body*. Concentrated proteins are more difficult to digest than most other foods, and must be consumed within individual limitations rather than according to charts.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > 10. Vitamin-B12

## 10. Vitamin-B12

Some people are fearful that a diet which does not include animal proteins will be deficient in Vitamin B-12, and that they may become victims of pernicious anemia. Beef and beef liver are said to be the finest sources of B-12. Well, where does the herbivorous cow get this vitamin? Vitamin B-12 is manufactured by the friendly bacteria in the animal's intestinal tract. This is true for all vegetarian animals, including the human being, as well.

A deficiency of Vitamin B-12, which is a forerunner of pernicious anemia, is not necessarily due to dietary inadequacy. A report released from a Vitamin B-12 Conference stated, "Pernicious anemia appears to arise not from shortage in the diet, but from impairment of the ability to absorb Vitamin B-12." (Proceedings of the Nutrition Society, 71st Scientific Meeting, London School of Hygiene and Tropical Medicine, January 5, 1952, p. 295)

Study after study has shown that the deficiency of Vitamin B-12 is due to the lack of absorption of the vitamin from the intestinal tract, due to the absence of "intrinsic factor," a substance which is normally present in the gastric juices.

Putrefactive bacteria can destroy friendly bacteria, thus inhibiting the synthesis and absorption of Vitamin B-12. The principal cause of putrefaction in the digestive tract is the ingestion of cooked animal protein (though putrefaction can occur as a result of bad food combining, overeating of any concentrated protein foods, chemical additives and drugs).

There have been repeated instances of improvement in the condition of the blood as a result of fasting, plus subsequent improvement in the diet, especially when flesh foods are eliminated.

The myth that plants do not contain B-12 has been propagated and fostered by vested interests. The truth is that B-12 is found in plants in very small amounts. This is consistent with the fact that our need for Vitamin B-12 is miniscule (*under* one microgram (a millionth of a gram) daily, and the body can store it for two to eight years. (Vitamins of the B Complex, 1959 U.S. Department of Agriculture Yearbook of Agriculture, Section on Food, pp. 139-149) Robin Hur's article in this lesson suggests that our actual need for Vitamin B-12 is considerably less than one microgram per day.

Vitamin B-12 has been found in significant amounts in many plant foods, some of which are bananas, dates, greens, peanuts, and particularly sprouts and raw sunflower seeds.

A correspondent to the *New England Journal of Medicine* (12/7/78, p. 1319) notes that vitamin B-12 is manufactured by micro-organisms, making it possible to obtain B-12 from certain seeds and nuts, and from soybeans. He also cites synthesis of the vitamin in the digestive tract of humans when adequate amounts of unheated seeds are eaten, and points to healthy babies who are breast-fed by strict vegetarian

mothers.

In studies on vegetarian humans, Dr. Wolfgang Tiling discovered the synthesis of B-12 in the intestines of children on a soy milk diet.

Dr. Karl-Otto Aly of Sweden examined the Hunzakuts and they showed no B-12 deficiency symptoms, though they have been almost 100% vegetarians for 2,000 years.

Dr. Alec Burton (Australian Hygienic professional) has seen countless people go for 25 to 30 years on vegetarian diets, and never display a deficiency of Vitamin B-12.

Current research at Loma Linda University found excellent B-12 levels for tested vegans (people who eat plant foods only), who eat all, or most, of their food fresh and unheated. Vitamin B-12 is water soluble, and therefore best obtained in raw foods.

Studies have demonstrated that Vitamin B-12 is heat sensitive and normal cooking can destroy as much as 89% of it. High consumption levels of fat and protein, refined foods and tobacco increase the need for B-12, while at the same time interfering with the synthesis and absorption of B-12. Thus the conventional meat-eater may indeed be a more likely candidate for Vitamin B-12 deficiency and pernicious anemia than the individual on an adequate vegetarian diet.

I have known a number of people who were found to be deficient in B-12 and who were receiving injections of this vitamin, but they were all flesh eaters. I have never known a Hygienist or vegetarian who was receiving these injections.

The list is long of children who nursed at their vegan and Hygienic mothers' breasts, and grew into exemplary specimens of perfect health: Dr. Virginia Vetrano's daughter and granddaughter, Helen Lamar's son, Dr. Bressak's children, Jay Dinshah's children, and others.

Vitamin B-12 (Cobalamin) is the only vitamin that contains a mineral—cobalt. It has been hypothesized that supplying this mineral to growing plants will increase their potential for being a source of the natural phenomenon which results in the production of Vitamin B-12.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > 11. Recap

## 11. Recap

Dr. Scharffenberg (p. 84, *Problems with Meat*) says: "The reality of the problems" (with meat-based diets) "is evident in the high mortality from cancer and atherosclerosis, among other disease problems, which makes it tragically obvious that it is not easy for the average person to learn how to eat properly on a meat diet."

A summary of the specific health reasons for eliminating flesh foods from the diet follows.

1. Flesh foods cause putrefaction by decomposing in the intestines, reducing the functioning of intestinal flora, and interfering with the synthesis and utilization of Vitamin B-12.
2. Their byproducts of toxic substances (uric acid, purines, etc.) and carcinogens cause degenerative diseases.
3. Saturated fats from meat produce abnormal cholesterol deposits, causing heart and arterial degeneration.
4. Meats contain parasites, chemicals and hormones, which damage the body and cause disease.
5. Diseased animals pass their diseases on to humans.
6. Flesh foods provide a favorable medium for the multiplication of the bacteria of disease.
7. Flesh foods lessen the resistance of the body to disease.

8. Vegetarians have stronger bones.
9. Meat-based diets present complex and grave nutritional problems.
10. People who eliminate meat from their diets are better nourished, and have better health and greater longevity than meat eaters.

As indicated at the beginning of this lesson, there are many other arguments against the use of flesh foods. In addition to the reasons listed there (that are not specifically health-related), the following should be included:

1. The lack of strength and endurance of meat-eaters, compared with vegetarians, has been repeatedly demonstrated (e.g. Olympic champions, etc.).
2. A meatless diet is conducive to symmetry and normal development of the human body.
3. A meatless diet improves the various senses and renders them more acute.
4. Meat, being highly stimulating, tends to cause overeating and other excesses (e.g. alcohol).
5. Meat-eating influences the mental, emotional and moral life. Flesh foods tend to make a person pugnacious.

The poet Shelley maintained that there is no disease, bodily or mental, which a meatless diet does not mitigate. He said, "On a natural system of diet, old age would be our last and only malady."

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > 12. Questions & Answers

## 12. Questions & Answers

**How can I be sure I am getting enough protein? What percentage of the Hygienic diet should be concentrated protein—nuts, seeds or legumes?**

First of all, don't forget the considerable protein in sprouts, bananas, potatoes, and, of course, a variety of vegetables. Most foods (including fruit) contain some protein, even though they are not thought of as protein foods because they do not contain concentrated protein. Concentrated protein foods usually contain somewhere between eight and twenty-five per cent protein. Actually, the protein in the foods that are less concentrated is easier to digest and assimilate than that of any concentrated foods (concentrated proteins, starches, dried fruits).

Dr. Scharffenberg says that if 10% of a vegetarian diet contained concentrated proteins, the person would be getting approximately 56 grams of protein daily. If the concentrated protein were reduced to 5%, the individual would still be getting approximately 34 grams of protein daily—no deficiencies there! Even the Food and Nutrition Board regards 56 grams as the recommended daily allowance and 34 grams as the minimum required daily allowance. Hygienists know we need even less.

Dr. Scharffenberg calculates that about 28 grams would be enough to maintain nitrogen equilibrium, based on a calculation of a nitrogen loss each day equivalent to 20 grams of protein of 100% biological value. Hygienists know that the biological value of uncooked proteins is highest, and it is well-nigh impossible to come up protein-deficient on a Hygienic diet that includes a small percentage of concentrated protein foods. A vegetarian might be protein-deficient if he regularly ate a considerable percentage of "cheat foods" containing refined sugars and starches.

The following two studies indicate:

1. The average vegetarian ingests adequate amounts of protein. (Hardinge, M.G.; Stare, F.J.; "Nutritional Studies of Vegetarians, I. Nutritional Physical and Laboratory Studies." J. Clin. Nutr. 2:73-82, 1954.)
2. The amounts of amino acids in the diets of vegetarians not only meet the minimum requirements— they more than twice exceed them. (Hardinge, M.G.; Crooks, H.; Stare, F.J.: "Nutritional Studies of Vegetarians, V. Proteins and Essential Amino Acids." J. Am. Diet Assoc. 48:25-28, 1966.)

### **Can humans be infected with diseases of plants?**

There is absolutely no evidence that diseases of plants can be transmitted to humans.

### **I am under the impression that only hogs are injected with trichinosis—and that other meats do not carry these larvae.**

The trichinae do originate in the hog. But, in 1974, New Jersey had more cases of trichinosis from beef than from pork. It seems that kitchens use the same knives and meat grinders for the beef and pork, and the trichinae may be thus transmitted to the beef. Studies by the New Jersey Health Department and the National, Center for Disease Control showed that as many as 8% to 20% of stores had beef contaminated with pork. (National Communicable Disease Center: Trichinosis Surveillance, Atlanta, May 1969)

### **Is the "Prudent Diet" the same as the Hygienic diet?**

No, but it is several steps in the right direction. The Prudent Diet is one that was used by Dr. Norman Jolliffe of New York City's Bureau of Nutrition in an "anti-coronary" club. Dr. Jolliffe was successful in reducing the incidence of heart problems by one-half during a ten-year period. The Prudent Diet is low in meat, cholesterol, saturated fat and calories, and high in fruits, whole grains, vegetables and legumes.

### **How would you rate the health hazards of meat as compared to other health hazards?**

I believe Dr. Scharffenberg's Health Hazard Poll is fairly accurate. He rates the various health hazards as follows:

- 25% Tobacco
- 25% Meat
- 15% Dairy Products, Eggs, High-Fat Foods
- 10% Obesity
- 10% Lack of Exercise
- 15% Alcohol, Tea, Coffee, Stress, Sugar, Snacks, Lack of Sleep, etc.

Dr. Scharffenberg includes "No Breakfast" in the final 15%, which I left out, because Hygienists know this is definitely not a health hazard, but an excellent practice. I am in basic agreement with Dr. Scharffenberg on his other factors, except that I know that lack of exercise deserves a larger percentage. Alcohol, a metabolic poison, should also be much higher on the pole.

My Health Hazard Poll would look like this:

- 30% Tobacco and Alcohol
- 25% Flesh Foods

25% Lack of Exercise and Obesity  
10% Dairy Products and Eggs  
10% Tea, Coffee, Stress, Sugar, Snacks, Lack of Sleep, etc.

**Isn't it true that when meat is "bled," as in kosher meats, all or most of the toxic wastes are drained off?**

Some may be, but not enough to really matter, especially as far as urea and uric acid are concerned. Most of the flavor of meat is due to these wastes. If all the blood were really drained off, the meat would be almost tasteless. Besides, many of the waste products are trapped in the tissues themselves. In addition to the urea and uric acid, there are large amounts of adrenalin produced during the pre-slaughter and slaughtering, dead and virulent bacteria, contamination from fecal matter, and, of course, various chemicals and hormones. There is no way to make meat really fit for human consumption.

**I know that a vegetarian diet is said to regulate (or actually lower) the serum cholesterol level. Is there documentation for this claim?**

A diet high in fiber increases the amount of lipids (fatty substances) eliminated by the body in the feces. Plant sterols—substances with a chemical structure similar to that of cholesterol—appear to help in the regulation of the human cholesterol level. Pectin (contained in fruits and vegetables) has also been shown to actually lower abnormal serum cholesterol levels. Fifteen grams of pectin eaten daily (corresponding to the upper level found in natural fruit and vegetable diets) result in an average decrease by 5% of the serum cholesterol in a three-week period. (*Unmeat*, Stoy Proctor, p. 16.)

Four studies (among many others) which have been published and reported in scientific journals, documenting these phenomena, are listed below:

1. A. Keys, F. Grande, J.T. Anderson, "Fiber and Pectin in the Diet and Serum Cholesterol Concentration in Man," *Society for Experimental Biology and Medicine*, Proceedings, Vol. 106 (1961) p. 555.
2. A.R.P. Walker and U.B. Arvidsson, "Fat Intake, Serum Cholesterol Concentration, and Atherosclerosis in the South African Bantu," *Journal of Clinical Investigation*, Vol. 33 (1954) p. 1358.
3. C. Joyner, Jr. and P.T. Kuo, "The Effect of Sitosterol Administration Upon the Serum Cholesterol Level and Lipoprotein Pattern," *American Journal of the Medical Sciences*, Vol. 230 (1955) p. 636.
4. Knut Kirkeby, "Blood Lipids, Lipoproteins, and Proteins in Vegetarians," *Acta Medica Scandinavica*, Supplementum 443 (1966) p. 70.

**I have been under the impression that meat-eating maintains bodily heat in the winter, and in cold climates. I note that vegetarians often are bothered by air conditioning, while meat-eaters are comfortable.**

You have it backwards. Vegetarians maintain body heat well, while meat-eaters are continually in a more or less feverish condition.

Dr. Trall pointed out that ordinary vegetarian foods contain all the carbon and hydrogen requisite to sustain the animal (or human) heat in all climates, and under all circumstances of temperature; and if every surplus carbon or hydrogen is taken into the system, it is, of course, thrown off; and when a large amount of surplus carbon and hydrogen is taken, the labor of expelling it is attended with a feverish excitement—which, instead of warming the

body permanently, only wastes its energies, and renders it colder in the end. (Carrington, *The Natural Food of Man.*)

Carrington says, "All the conditions requisite for the due regulation of the animal" (including human) "temperature are: good digestion, free respiration, vigorous circulation, proper assimilation, and perfect depuration; in two words—*good health.*" (p. 115)

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #1: Osteoporosis: The Key To Aging by Robin Hur

## **Article #1: Osteoporosis: The Key To Aging by Robin Hur**

Robin Hur is the author of "*Food Reform, Our Desperate Need*"

Osteoporosis, which means "porous bones," is the foundation of the entire so-called "aging" process; it produces the decrepitness of old age and it leaves in its wake a maelstrom of age-related degenerative conditions. Osteoporosis results from an insidious process of bone demineralization, which, over a period of many years, robs the bones of up to half of their original calcium content. The bones are left frail and weak, and to make matters worse, much of the lost bone calcium ends up in the walls of the blood vessels, the skin, the eyes, the joints and various internal organs.

The calcium that finds its way to the blood vessels causes hardening of the arteries; that which ends up in the skin causes wrinkling. In the joints the errant bone calcium takes the form of arthritic deposits, in the eyes it takes the form of cataracts and in the kidneys and bladder it becomes what we know as stones. Thus, osteoporosis is (literally) the source of a broad range of degenerative processes.

The development of osteoporosis has now been linked to cancer, but even before the discovery of the cancer ties, gerontologists had concluded the "aging" process centers on the transfer of calcium from the hard tissues (bones) to the soft tissues (skin, arteries, joints, retina, etc.) It follows that keeping the bones intact, that is, prevent osteoporosis, is tantamount to preventing the degeneration of aging itself.

It is doubtful the bones of Westerners ever reach full maturity. It is beyond doubt, however, that at some stage of adulthood, their bone calcium begins to ebb and be carried away in the bloodstream. In time, the entire skeletal structure becomes porous, frail and weak. As members of that weakened structure, the vertebrae tend to yield to the load of the torso, so the back is wont to become crooked, compressed and painful. Such are the earmarks of osteoporosis, and with its onset, the individual tends to become stooped and normally loses inches off of his or her height. Spontaneous fractures of the vertebrae are common, as are fractures of the hips, arms, and legs. All of the bones are left vulnerable to breaks, which, when they do occur, are slow to heal.

A study at the University of Tennessee indicates that women usually develop osteoporosis following menopause but that men normally do not contract the disease until their early sixties. Other research indicates both sexes experience serious bone losses at much earlier ages.

Grim reports concerning the attrition of bone calcium in America should not be taken to mean that osteoporosis, nor for that matter what we call "aging," is unavoidable. Poor posture is the hallmark of osteoporosis, and Sula Benet describes the Abkhasians posture as "unusually erect, even unto advanced ages." Elderly Abkhasians are unbothered by spontaneous fractures, but as horsemen and mountain climbers, they do sometimes break bones and when such breaks do occur, they are wont to heal rapidly and completely, which would not be the case if they were suffering from osteoporosis.

Vilcabamba centenarians are, in Grace Halsell's words, "known to have healthy bones." Hundred-year-old Vilcabambans still work in the fields, bending the whole day, and show no ill effects. Ms. Halsell reports never having heard of an elderly Vilcabamban's having fallen and broken an arm, leg or hip. She adds that she saw not one Vilcabamban who limped or was disabled.

Other groups that manage to avoid osteoporosis include the Hunzas and Yucatan Maya. Like the Abkhasians and Vilcabambas, these groups live in traditional ways and take low-protein, primarily vegetarian diets. And from the way groups taking flesh-based diets decline with age, there is little doubt it is the diet of the Hunza, Abkhasians, et al. rather than their lifestyles, that enables them to circumvent osteoporosis.

The heavy meat eating Masai males, Eskimos, and Greenlanders apparently develop osteoporosis at very early ages. The Eskimos normally become bent, shrunken and disabled in their late 20s while Greenlanders become decrepit in their 30s. The most interesting case, however, is that of the Masai. The tribe's males spend their formative years roaming with their herds, drinking the animals' blood and milk, and eating only small amounts of plant foods. Then, at the age of 20 or so, they take off to do a two-year stint as warriors, during which time they try to live on flesh alone. Following the warrior stint, and while still in their early 20s, they migrate to the tribes' villages, arriving at the villages with bent backs, diminished heights and debilitated bodies, whereupon they are cared for by the villages' women until they die. Now here's the rub: the tribe's females, who remain in the villages while the males are out subsisting on flesh and making war, raise and eat plant foods, and remain remarkably free of osteoporosis.

Research linking osteoporosis and high-protein diets is upending the foundations of modern nutrition. In the words of Drs. Ammon Wachman and Daniel Bernstein of Harvard, "the association (of meat-based diets) with the increasing incidents of bone mass loss with age is inescapable." They go as far as to say "it might be worthwhile to consider" a diet emphasizing fruits and vegetables and only a moderate amount of milk. The head endocrinologist at the Jewish Hospital in St. Louis acknowledges that "vegetarians suffer less osteoporosis than people who eat lots of meat and have high-protein intake." The relationship between high-protein intake and loss of bone calcium was the subject of a major address before the nation's nutritionists in April. The speaker was Dr. Helen Linkswiler who, as head of the Nutrition Department at the University of Wisconsin, pioneered in protein-calcium research. Dr. Linkswiler and her colleagues are firmly convinced high-protein intake causes the bones to ebb.

Sharing that opinion are a growing number of nutritionists including two of the world's leading authorities on protein and calcium, Doris Calloway of Cal-Berkeley and Mark Hegsted of Harvard.

In the first protein-calcium studies (now just eight years old) it was found that a protein intake of 140 grams per day caused young men to lose their bone calcium at a rate of 3% of total bone mass per year. The subjects evidenced no capacity to adapt to the high protein intake, and at the rate they were losing calcium, they would have had no bones at all by their mid-fifties.

Subsequent studies showed young men experienced no bone losses when they were put on diets containing less than 50 grams of protein per day; but when their protein intake was raised to 95 grams per day, their ability to keep their bones intact depended on the amounts of calcium and phosphorus, the 95 grams of protein per day resulted in relatively small losses of bone calcium. But when the diet contained more realistic (albeit still favorable) levels of calcium and phosphorus, the 95 grams of protein per day resulted in calcium losses amounting to 2% of total body calcium per year. At that rate it would take the young men about 15 years to develop severe osteoporosis. It should be pointed out that the average protein intake of young American males exceeds 95 grams per day.

Studies with young women began only recently, and their peak protein intake was scaled down to 100 grams per day. It had been predicated that the presence of female sex hormones would protect the young women from serious bone losses, but this proved not to be the case. The young women responded to 100 grams of protein daily in essentially the same way the young men had responded to much higher intakes.

It is noteworthy that every single individual involved in one of these protein-calcium studies has responded to increased protein intake with decreased calcium retention. And, so far, all such studies have been conducted with young adults, who by virtue of their age, should be relatively resistant to bone deterioration. What is more, the reported losses were, in all cases, understated, for they took no account of sweat losses, nor did they make any allowances for any calcium that may have been deposited in soft tissues (measurements focused on what was excreted rather than what ebbed from the bones.) And with one exception, the experimental diets were fortified against loss of bone calcium through the presence of abnormally low amounts of phosphorus. Thus, the results of these studies actually tend to *understate* the effects of protein on the bones.

## **Phosphorus vs. Calcium**

There is, of course, more to "protein foods" than just protein. Animal products are all high in phosphorus, and with the exception of dairy products, they all have very low calcium-to-phosphorus ratios. All animal products are high in chlorine and sulfur, low in manganese and magnesium, and with notable exceptions, they are high in fat and low in Vitamin C. Surprisingly, everyone of these characteristics tends to impair bone development and/or retention.

The relationship of phosphorus intake vis-a-vis calcium intake to bone development and retention has been the subject of extensive research. It has been found that when the phosphorus content of the diet is not excessive, a high calcium-to-phosphorus ratio promotes strong bones.

When, on the other hand, the phosphorus content of the diet is very high, bone deterioration is unavoidable.

High-phosphorus diets effect substantial rises in the level of phosphorus in the blood; and in what amounts to an effort to control the ratio of calcium-to-phosphorus in the blood, the body responds to a rise in blood phosphorus by removing calcium from the bones and releasing it into the bloodstream. Boosting intake of conventional calcium sources (dairy products) does nothing to alleviate the situation. Calcium absorption drops sharply when intake is elevated, so little of the added calcium actually reaches the bloodstream. Moreover, dairy products are high in phosphorus as well as calcium, and almost all of the phosphorus does get into the bloodstream. Thus the addition of dairy products to a diet already high in phosphorus may actually speed up the rate of bone deterioration.

Studies indicate the phosphorus content of typical diets is 20 to 100 percent above safe levels; moreover, calcium-to-phosphorus ratios are less than half what they should be. Meat and dairy products account for two thirds of the total phosphorus in typical diets. Eliminating just the meat would reduce total phosphorus intake to acceptable levels—it would also bring a dramatic increase in calcium-to-phosphorus ratio.

Phosphorus tends to acidify the blood. Chlorine and sulfur have the same effect, so when intake of one or more of these three minerals is excessive, the body goes in search of a buffering agent. Without some means of buffering the blood, a single overload of one or more of these minerals could cause severe acidosis, and even death. The body contains four minerals that can act as buffering agents, but only two of these, namely potassium and calcium, are available in quantity. Unfortunately, excesses of the acid-forming minerals are almost always accompanied by a rise in blood potassium levels, and since further increases in serum potassium could have dire consequences, the body tends to call upon its calcium bank (i.e., the bones) for a buffering agent.

The mechanism that initiates the removal of calcium from the bones also puts a halt on the excretion of calcium by the kidneys. The result is a rapid rise in blood calcium, which tends to bring about the deposit of calcium in the soft tissues in the form of kidney and bladder stones, arthritic deposits, etc. Thus, the acid-forming minerals are capable of triggering the entire "aging" (i.e., calcium transfer) process.

Foods that contain an excess of the acid-forming minerals (phosphorus, chlorine and sulfur) over and

above the alkaline-forming minerals (calcium, potassium, sodium and magnesium) are said to have an "acid ash." Foods that are on balance, alkaline in nature are said to have an "alkaline ash." Protein itself forms an acid ash and this may explain why high-protein intake causes the bones to give up calcium.

All so-called "protein foods," including milk, tend to acidify the blood. Without exception, they are rich in the three acid-forming minerals; moreover, all of their chlorine, and a major segment of their phosphorus, lies external to their protein. Thus, they have an acid-forming capacity which is independent of their protein. It follows that protein foods, such as beef and eggs, would be expected to cause even greater bone losses than isolated protein extracts, which served as the principle sources of protein in all but one of the aforementioned protein-calcium studies. And in the one study in which meat did serve as the protein source, calcium losses were indeed accelerated.

The addition of fruits and vegetables to the diets of young men taking 140 grams per day cut their bone calcium losses by 25 percent. Fruits and vegetables have an alkaline ash, so their addition to an acid-forming high-protein diet would tend to cut the need for bone calcium as a buffering agent.

Typical diets have a strong acid ash. The first step to alleviating this situation is to eliminate from the diet those items with really high acid ashes, namely meat, eggs, fish and poultry products. Without these, normal diets would be tolerably close to neutral and the individual would be in a position to work towards a truly good diet—which means, among other things, an alkaline ash diet.

Inactivity is still another, and possibly important, cause of skeletal erosion. Extended bed rest led to calcium losses at a rate of 6% of total bone mass per year in young men. On the other hand, exercise tends to enhance calcium retention and it has been shown that low-protein, low-fat diets boost endurance and engender spontaneous activity. High-fat, high-protein diets cut endurance and promote inactivity. It's just not a good day for the meat group.

The integrity of the bones depends on the supply of a number of minerals, including manganese and magnesium. An adequate supply of manganese enhances the strength and density of developing bones, while an adequate supply of magnesium tends to prevent bone calcium from ending up in the kidneys and bladder as stones.

Ironically, cow's milk is used to induce both manganese and magnesium deficiencies in animals.

Manganese-deficient milk left young rabbits with bowing front legs and a bone structure that was weak and porous. Magnesium-deficient low-fat milk induced kidney stones in 97 percent of a group of rats; it can offer no solace to milk drinkers that researchers believe the protein in milk played a role in the stone formation. In all fairness, though, it should be pointed out that milk is not the only dietary item that is low in manganese and magnesium: all animal products are markedly low in both minerals; in fact, the entire American diet is dreadfully low in both.

High-fat intake tends to inhibit calcium absorption through the formation of insoluble calcium compounds of the gut. Calcium absorption is aided by the presence of Vitamin C which tends to keep calcium in an absorbable state. It hardly needs pointing out that animal products are grossly high in fat and scurvy-low in Vitamin C.

The ties between animal products and the entire "aging" process (i.e., the transfer of calcium from the bones to the soft tissues), and osteoporosis in particular, make the cornerstone of the "four basic food groups" look like a tombstone. To recoup, *normal diets contain enough protein to produce rapid bone losses, even among young adults.* They also contain enough phosphorus to cause debilitating bone deterioration; and they have a calcium-to-phosphorus ratio that would be expected to both thwart bone development and speed deterioration. Normal diets have an acid ash capable of producing both bone deterioration and the accumulation of calcium in the soft tissues:

Animal products are the principle source of the protein, the phosphorus, the low calcium-to-phosphorus ratio, and the acid ash in normal diets. What is more, animal products tend to effect bone-degenerating inactivity and deficiencies of bone formation-dependent manganese and stone-preventing magnesium.

On top of this, animal products are very low in Vitamin C, which aids calcium absorption, and overloaded with fat, which inhibits calcium absorption. It's a one-sided picture, but it's a one-sided scene—and it bears a message of hope.

We don't have to face advanced age as less than skeletons of our former selves. It is clear, though, that walking tall and, painlessly into the years ahead requires our abstaining from meat, eggs, poultry and fish. Little is to be gained by switches to meat substitutes, synthetic eggs, etc.—we need to get away from the protein, the fat, the phosphorus and the acid ash, not simply take them in "vegetable" form.

We do need a good source of calcium in the diet, but we don't need milk. Milk is, after all, merely a substitute, and a poor one, for dark green leafy vegetables. Collards, parsley, turnip greens, watercress, kale, mustard, spinach, etc. provide twice as much calcium as milk and yet they contain considerably less phosphorus. They have calcium-to-phosphorus ratios three to four times that to milk. And unlike milk, greens have a strong alkaline ash; what is more, they are excellent sources of manganese, magnesium, and Vitamin C. They are also free of the troublesome protein, fat and cholesterol of milk. As for the problem of excess protein, replacing the milk and cheese with a few ounces of greens (which is all that is necessary) would cut protein intake by 10-15 grams per day.

A few greens, including spinach, are high in oxalic acid, which may reduce the availability of their calcium. It is advisable to include at least one oxalate-free green (see earlier lessons on oxalic acid and which vegetables contain it and/or other irritant properties) in the diet, but there is no reason to avoid these vegetables *completely*. Vegetables are best taken raw, of course. Take them in salads, or enjoy their company and taste right in the garden.

We are going to hear a good deal more about osteoporosis during the next few years. The protein-calcium studies have upended the foundations of modern nutrition. Critics simply can't find any loopholes in the results. No exceptions. No extenuating circumstances. No inconsistencies. In the words of one of the nation's best known nutritionists: "I now realize we know almost nothing..." She went on to extol dark green leafy vegetables, leaving the impression they were a new thing to her.

It's happening. Meanwhile don't be fooled by claims you need a "protein source." Stick with the juices, fruits, greens and sprouts; they'll keep your bones intact, your soft tissues soft and your years without worry.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #2: Vegetarian Mother's Milk Safer

## **Article #2: Vegetarian Mother's Milk Safer**

The breast milk of vegetarian women is significantly safer than that of meat-eating women, according to a study conducted by the Washington-based Environmental Defense Fund (EDF).

Last June, government and university researchers testified before a senate subcommittee that it is difficult, if not impossible, to find safe milk for new-born infants anywhere in the world. The researchers cited an Environmental Protection Agency (EPA) study conducted in 1975 which indicated that 99% of breast milk samples taken from more than 1,400 nursing mothers in 46 states, were contaminated with pesticides, such as Dieldrin and DDT, and other industrial compounds such as polychlorinated biphenyls (PCBs).

PCBs are suspected carcinogens, and in low doses can cause sterility in animals. They are now widespread in the environment, because of accidental spills and deliberate, covert dumping of the chemicals into public water supplies.

For instance, a number of factories along the Hudson River have for years been circumventing state

water purity laws by processing PCBs, benzene, chloroform, and other chemicals through municipal sewage treatment plants— despite the fact that such plants are incapable of filtering out toxic chemicals before dumping the water into the river.

This fall (however), the EDF tested breast milk samples from 50 predominantly vegetarian women, and found that the levels of pesticides such as DDT in their milk were only 1/3 to 1/2 those of mothers eating a conventional diet.

The levels of PCBs, however, were only slightly reduced from the average breast milk concentration of 1.8 parts per million—10 times higher than the maximum amount considered "safe" for babies.

The women chosen for the study ate milk and dairy products as well as fruit, grains, and vegetables, and a few ate fish as often as once a week.

The EDF researchers say they cannot explain why not eating meat should make such a difference in the pesticide levels of nursing mothers. They suggest that it's probably that vegetarians eat more organically grown foods (foods grown without pesticides) than do most carnivores.

The foregoing article and headline (with a rather sensational sub-heading, "Meateaters Breast Milk Laced with Pesticides") was found in a recent Earth Watch section of New Age Magazine.

It may be that some vegetarians eat more organically grown food, but this is a lame explanation for the reduced levels of pesticides as noted. In the last issue of VV, Nat Altman noted that dairy products contain "only about 2/5 the pesticide residues as (compared to) red-meat, fish, and poultry. Oils, vegetable fats, and leafy vegetables contain about 1/7 as much; fruits and legumes are about 1/8 as much; and the figure for grains and cereals is only 1/24 the pesticide residues found in meat."

This is due to the concentrating factor as the contaminant goes through the additional link in the ecological chain; that is to say, an animal (or human) is likely to concentrate the pollutant in its body; it may also dispose of some of it in milk. Actual tests in Britain have shown the pesticide residue level in humans to be highest in meat-eaters, lower in lacto-vegetarians, and lowest in total-vegetarians. It is very likely that the PCB levels would follow a similar pattern, as PCBs are not just industrial pollutants but are largely produced by the breakdown over the years, of DDT in the soil and environment.

Given the many proven advantages of breast-feeding by a healthy human mother, we do not feel that vegetarians should be stampeded into forsaking this practice that is so potentially beneficial for both mother and baby. Considering that the pesticide (and probably PCB) level of vegetable-source foods is such a small fraction compared to that of even the dairy products, it may well be considered by even lacto-veg. mothers to substitute leafy greens and other rich sources of nutriment, for dairy products, at least during pregnancy and lactation. Also, we cannot refrain from commenting that even eating fish "as often as once a week" could easily be a factor in keeping PCB levels up.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #3: Booklet Review - Meat And The Vegetarian Concept, Part I

### **Article #3: Booklet Review - Meat And The Vegetarian Concept, Part I**

This review concerns the 20-page pamphlet, *Meat and the Vegetarian Concept*, published by the National Livestock and Meat Board.

Intended to refute various aspects of meatless diets, it has been circulated extensively to educators, nutritionists, media people, and other individuals throughout the USA.

The text itself is carefully written and attractively presented, and at first glance seems to offer very

convincing arguments in favor of eating meat.

However, a careful reading reveals a plethora of inaccurate and incomplete data, outright distortion of fact, and even the tendency to create an argument where none, in fact, exists.

Because of the extensive distribution of this pamphlet and the highly misleading statements it contains, NAVS feels that a swift and factual response is warranted.

As the pamphlet takes a rather disorganized "shotgun" approach, a point-by-point analysis would be impractical. However, NAVS has requested 3 well-known vegetarians active in the movement to comment extensively on the main points, making full use of documented material from non-vegetarian as well as vegetarian sources.

The three are: Nathaniel Altman (author of *Eating For Life*; NAVS board member); Robert Pinkus (director of Metropolitan Veg. Assn.); and H. Jay Dinshah (Pres. of NAVS).

NAT—Very often, meat industry spokespeople, such as the National Livestock and Meat Board, find it in their interest to classify vegetarians along with those few enthusiasts of the radical and nutritional unsound "Zen macrobiotic #7 diet," which calls for the consumption of only brown rice. It should be made clear that macrobiotics and vegetarianism are not the same, as many macrobiotic diets involve the liberal consumption of seafood, such as fish, clams, shrimp and other crustaceans. In addition, certain vegetables such as eggplant are enjoyed by vegetarians but frowned upon by macrobiotic enthusiasts as "poison." Fruit and salads are also generally avoided.

Thus, it is absolutely necessary to define our terms: Vegetarians do not eat the meat of domestic or other animals, whether it is beef, pork, veal, lamb, poultry, fish or other "sea food." Most vegetarians—perhaps 90-95%—are either lacto or lacto-ovo vegetarians, eating such foods as eggs and/or dairy products in addition to plant foods. A small percentage of vegetarians—called "total vegetarians"—abstain from animal foods altogether, and consume only plant-source foods, such as grains, legumes, nuts seeds, fruits, and vegetables. "Vegans" are total vegetarians who also refuse to use nonfood animal products, such as leather, furs, silk, wool, and soon.

BOB—In his forward to this pamphlet, NLSMB President David Stroud (whose commercial interest in promoting meat-eating seems obvious) sets a very low tone in trying to equate vegetarianism with some vague and unspecified "commercial interest"; with "food fadism and nutrition quackery, higher grocery bills and complicated meal planning," as well as potential poor nutrition. *All of which could hardly be further from the truth.*

While commercial interests have always abounded in human endeavors, seldom have they been less important as motivations (when they exist at all) than in today's vegetarian movement, either with the average vegetarian or the more outspoken vegetarian advocates.

As we get deeper into this curious pamphlet, we shall soon see where the label of "nutrition quackery" rightly belongs.

A considerable saving can be expected on grocery bills for persons changing from a meat-based diet to a well-planned nonmeat diet, as noted briefly in *Facts of Vegetarianism* (10-cent booklet from NAVS).

Meal planning can, if anything, become much simpler, although with the tremendously increased available variety of natural non-animal foods that many newcomers to vegetarian living seem to "discover" for the first time in their lives, it often happens that one soon discovers that vegetarian dining can also be more fun and much more delicious.

VEGETARIAN VOICE—On page 6, the NLSMB dismisses, in a single paragraph, religious reasons for abstaining from certain or all types of meats, calling these "religious taboos." Is the characterization fair and is it accurate?

BOB—The pamphlet cites Hindus, Moslems and Jews, and 7th-Day Adventists, in regard to opposition to some or all types of meat. Conveniently omitted are such groups as Trappist and Benedictine monks,

Jains, Buddhists, Essenes, and others who at various times in history help to fill out the picture of widespread partial abstinence or outright injunction against flesh eating.

JAY—First, I would point out that "poor sanitation" in meat handling is hardly limited to Biblical times or the Middle or Far East as this paragraph implies: indeed, it does not seem to be altogether unknown even nowadays.

We may sympathize with the embarrassed reluctance of the NLSMB to go into further detail about the shellfish, the swine, the vulture, etc., said to be stamped "unclean" and declared by their own Creator to be unfit for human consumption (even under the more liberal demands for flesh-eating raised by erring humanity); this was clearly due to their being much less fastidious in their dietary habits—i.e., the consuming of river sewage, the omnivorous scavenging of fecal matter or carrion—than the vegetarian creatures in general. (See Deuteronomy 14:3-21; also see Genesis 1:29-30.)

Doubtless, many of our friends in the movement who happen to be 7th-Day Adventists, will be surprised to be singled out and to learn that their reason for not eating meat is supposed to be "as an expression of their religious devotion."

I commend to you the chapter on Flesh As Food, including, "Reasons for Discarding Flesh Foods," in *The Ministry of Healing*, by Ellen G. White: the reader may judge whether the health reasons for vegetarianism presented so eloquently therein are mere superstitions or "religious taboos." But it will be crystal clear why the meat promoters may wish the public to think so, especially when one considers the long and illustrious tradition of SDA researchers, dieticians, and M.D.'s in documenting and publicizing the superiority of vegetarian living, purely from the secular standpoint of better health and longevity.

In a recent year, the livestock feed production alone in the U.S. was 165 million tons, not including the wheat consumed by animals. One half of the total of all U.S. crops are fed to animals, including 86% of corn, oats, and barley, 90% of the non-exported soybeans, and 42% of the wheat Americans consume, for an overall consumption picture of 78% of all U.S. grains going to feed animals.

Nor does this include the huge areas of land misused for grazing purposes. And all this is IN ADDITION to any molasses-soaked old newspaper, silage, excrement, or whatever else they now call "recycled" feed, either experimentally or commercially.

JAY—Obviously, the 3:1 ratio cited in the NLSMB booklet refers to the very "best" meat producer—the chicken—although all fowl and fish are conveniently omitted when the board wants to convince Americans that they aren't eating enough meat (p. 10). We are not going to say that the use of a 3:1 figure is a deliberate attempt to distort the facts; an alternative explanation would be that the experts of the National Livestock and Meat Board just don't know the difference between a chicken and a steer, and hope the public will be just as much in the dark. So it might be an honest mistake.

Of course, it is not just vegetarians who are drawing the public's attention to "preposterous stories" of the waste of grain in feeding food animals. But it is the practice, not the stories, that we find preposterous. The figures that Nat and Bob gave are corroborated in the special section on the "World Food Crisis" in the Nov. 11, 1974, *Time* magazine. It notes the 400 lbs. of grain eaten by a person in a year in a poor country versus an American consuming "five times that amount, mostly in the form of grain-fed beef, pork and chicken. The industrial world's way of eating is an extremely inefficient use of resources. *For every pound of beef consumed, a steer has gobbled up 20 lbs. of grain.* Harvard nutritionist Jean Mayer notes that "the same amount of food that is feeding 210 million Americans would feed 1.5 billion Chinese on an average Chinese diet." This is a food ratio of 7:1, and it would be much worse but for the fact that "meat-eaters" do not eat only meat, but rather a mixed diet, and this helps keep the ratio down to "only" 7-to-1 in this case.

The booklet does seem to confuse the protein-conversion ratio with the grain-to-meat conversion ratio, which is obviously not quite the same thing. In the 20 lbs. of grain cited by *Time* magazine, there might run, say, 2 $\frac{1}{2}$  lbs. of protein (about 1/8). In the single pound of beef produced, it might run around 1/6 lb. of protein. So the actual protein conversion ratio (grain:beef) would run about 15:1, close enough to the

17:1 cited by Nat (allowing for reasonable variables), but five is as great as the meat propagandists would have us think, by their literary legerdemain of just lumping everything together as "meat" and claiming the greatest "efficiency" as if it represented an average. I feel we have every right to "beef" about this figures finagling, because that's just too much bull to hide behind a little chicken.

Averaging out the food waste factors on the various types of meat—even including fowl—in the quantities actually consumed, you would probably come up with a rule-of-thumb average in the vicinity of that of Prof. Isaac Asimov's estimated 90% waste, or 10:1 ratio overall (see "Our Wasted Land" in *Facts of Vegetarianism*, published by NAVS). You know, Dr. Asimov is a noted science writer, who is also in the top ranks of science-fiction authors. He used to be my favorite in the latter field until recently. But now I eagerly await further literary efforts of the NLSMB, as I find their creative style of subtly blending science with fantasy to be so much more imaginative and entertaining than even that of Dr. Asimov, providing one does not take them too seriously, of course.

In all candor, though, I must admit that we vegetarians must be stronger of conscience than of stomach. Personally, I don't think I would have the guts to stand right up and look down on a starving sister or brother and say right out that I have "only" three lbs., or 10lbs., or 20lbs. of food, but I'd rather throw it to the pigs or the cows than share it with a human being. I don't think I could bring myself to brag about the efficiency of "only" throwing two chapatties out of three into the dung-heap. It really takes a rare kind of cool to pour water from your overflowing canteen onto the desert sand in front of a fellow human dying of thirst. It really must have taken a lot of nerve for the NLSMB to make a statement like that.

This kind of machismo, we can all live without. But the real question is: can this hungry world live with it?

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #4: Booklet Review - Meat And The Vegetarian Concept, Part II

## **Article #4: Booklet Review - Meat And The Vegetarian Concept, Part II**

—continued from previous issue. Comments by Nat Altman, Bob Pinkus, and H. Jay Dinshah.

VV—On Page 7, the booklet (published by the National Livestock and Meat Board) claims that "the biological quality of protein found in animal foods is superior to that in vegetables" and implies quite strongly that vegetarianism is a major reason for people in developing nations suffering "rampant malnutrition—stunted growth, small brain development, and the disease kwashiorkor...."

NAT—What was omitted was the fact that there is absolutely no connection between "rampant malnutrition" etc., and a Vegetarian diet. The basic factors in malnutrition are either lack of the availability of nutritious vegetarian food or inadequate knowledge of nutrition.

Nutritional studies on the Hunzas, the Otami Indians in Central Mexico, the "old men in Vilcabamba," Ecuador, certain tribespeople of South Africa, young girls in Appalachia, and other people in various parts of the world, all showed that one doesn't need meat to ensure an adequate intake of protein, calories, fat, and essential vitamins and minerals.

The booklet also failed to note the well-known fact that the biological quality of those plant proteins that are low in specific amino acids dramatically improves when combined with other plant-source foods, such as rice and legumes, or grains and legumes. Most predominantly vegetarian people have been habitually combining these foods for thousands of years, and have enjoyed sound nutrition and excellent health.

The argument that because animal protein is much closer to that of the human body makes it preferable to plant protein is absurd. If this were true, all animals would be carnivorous if such a bizarre criterion needed to be met.

JAY—Worse than that, Nat; it's a powerful argument for universal cannibalism. What could be closer to human flesh than human flesh?

But this whole scare about protein is pretty much of a red herring. It is most inaccurate to make a blanket statement that animal protein is superior to vegetable protein. They talk about "vegetables" as if vegetarians only ate carrots and turnips. Nuts and seeds generally have protein of roughly equivalent biological value to meat, and in greater proportion than in meats generally. Muscle meat is "deficient" compared to organ meat. And even leafy greens have a moderate proportion of protein of very high biological value. Nor does the term "incomplete" mean a protein is valueless by itself; only that even a single essential amino acid is a percentage point or more less than an arbitrary dividing line of 60% (for adults) or 70% (for children) of what is considered an ideal balance. The difference between a "complete" protein and an "incomplete" protein is not—as some would like us to believe—the difference between 100% and zero: it is often so marginal as to be meaningless for any practical relationship to the actual needs of the human body.

Nor is it even necessary that all the essential amino acids be present in the same meal (let alone the same food), as the body recycles amino acids from dying cells and maintains, in effect, a pool of amino acids. (See p. 383 of *Laurel's Kitchen*.) For further information on vegetable proteins and their complete adequacy, see *The Protein Problem*, *The Happy Truth About Protein*, *About Protein* (in *Facts of Vegetarianism*), and the *Vegetarianism* special supplement to *Life and Health* magazine, all available from NAVS.

As for their view of malnutrition, they seem to just throw in "a deficiency of calories" as if it were a separate problem from the better-publicized protein deficiency. Actually, the former usually accompanies the latter, as it is a matter of just too little food available (see p. 385, *Laurel's Kitchen*), a fact the meat people seem understandably anxious to obscure.

This reminds me of old Calvin Coolidge's sage observation that when a lot of people were out of work, the result was unemployment. The NLSMB wants us all to know that when people are too impoverished to obtain *enough* vegetarian food, the result is malnutrition and starvation. But as we shall see, their "solutions" to such human difficulties seem more in line with the naive advice given by another historic figure, Marie Antoinette.

VV—On page 6 of the booklet, it is claimed that the conversion ratio is 3:1 for vegetable protein to animal protein in raising animals for food, and that much of the protein for feeding animals is obtained by recycling otherwise inedible "wastes" for feed.

NAT—Actually, the demand for meat in the USA contributes markedly to rampant malnutrition in the developing countries. *Despite a world food deficit of over ten million tons, over 580 million tons of grains were fed to livestock in a recent year.* In the U.S. alone, approximately 87% of all the corn, oats, barley, and grain sorghum crops are fed to livestock, not directly to people.

In converting this high-protein feed into meat protein, the productivity rate is far different from the 3:1 ratio claimed.

According to the June 6, 1968, issue of *Chemical Industry* it takes 1250 lbs. of plant protein to produce 75 lbs. of beef protein, an efficiency factor of just 6%, or a ratio of 17:1. The corresponding efficiency factor for lamb is 9% (11:1); for pork, 15% (6 2/3-to-1); while the most "efficient" protein converter is chicken, and even that only yields 2.5 lbs. of protein for every 8 lbs. of plant protein consumed, a factor of 32%, or a little less than 3:1. Something they do not mention is another serious barrier to good nutrition in developing nations. It is a well-known fact that many of the developing countries are utilizing their best land for cattle raising for export to the USA, instead of using this land for growing staple crops which could feed their hungry people.

In Guatemala, for example, where 75% of the children under five years of age are malnourished, nearly 23 million pounds of meat were sent to the USA from January to November 1976 (Foreign Ag. Calendar, USDA, of Dec. 1976). At present, Guatemala has a shortage of low-priced corn and beans, the staple foods of the peasant population.

BOB—The meat people admit that the ratio for protein conversion is "only about 3:1." Even if true, what would be moral about even that ratio, in a world in which each year millions of humans die of diseases related to malnutrition?

A fact ignored by the booklet is that in a country such as India, the average person can only get about 400 pounds of grain per year, but can live by eating it instead of feeding it to animals. In America, the average meat-eater consumes 2000 lbs. of grain per year, but only 150 lbs. direct and the rest second-hand through animal products.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #5: Scientific Vegetarian Nutrition

## **Article #5: Scientific Vegetarian Nutrition**

(NAVS Western Coordinator and Board Member Dixie Mahy reports on a 2-day class presented by Dr. Aly at the 23rd World Vegetarian Congress....)

Although a qualified medical doctor Dr. Aly utilizes vegetarian diet, fasting, and non-drug therapy. He stated that scientific thought is just now coming to favor vegetarianism, and that early scientific errors have been made which have taken a long time to correct.

Error #1) Scientists thought that since protein was the most important nutriment in the body for growth and repair, and that since animals were rather similar in construction to humans, meat was therefore the best food for the human body.

The error was that they did not realize that the body can build up its own human protein from proteinaceous food sources within the vegetable kingdom.

Error #2) Scientists thought that by refining carbohydrates—which the body needs for energy—it would make them easier to assimilate, e.g.: pure white sugar, white flour, polished rice, etc.

The error was that, most unfortunately, the vitamins, minerals, and enzymes are largely destroyed in refining, processing, or even in long cooking; and the body needs these nutriments.

Error #3) Scientists thought the body needed more dietary fat than it actually does, and began recommending too much in the diet.

The error was that, although the body needs fats, it gets an excessive amount of saturated fats as a result of high meat intake and saturated oils as a result of processing.

## **The Protein Myth**

Dr. Aly discussed more fully the "protein myth" perpetrated by western scientists, who made two major errors on protein: As previously noted, proteins from the vegetable kingdom were considered inferior; and the protein minimum daily requirement was set at a figure far too high for the body's actual requirements. (In addition, it should be noted, the RECOMMENDED daily amount was arbitrarily set at DOUBLE the supposed minimum amount proven adequate, -ed.)

In the East, the question was, "How little protein do we need?" But in the West, the question was "How much protein do we need?" Scientists are now starting to slowly correct their mistakes. Ironically, for

example, they once recommended the optimum "to make sure" but today modern scientists recommend the minimum of before (1/2 the former *recommendation*) as the optimum of today.

Dr. Aly went on to state that meat is not a good energy source as it is not easily combusted and needs several enzymatic processes to metabolize, with lots of waste products, nitrogen waste, uric acid, and urea, which the body disposes of with difficulty. Waste from protein cannot be disposed of so easily as waste from carbohydrate. (Consider that carbohydrate breaks down easily with water,  $H_2O$ , as a waste product which the body can easily get rid of through perspiration, or via the lungs or kidneys.) On the other hand, the kidneys are the only way of eliminating protein waste. When there is an overload, material is stored in all connective tissues, etc., throughout the body. This overload along with no exercise, will eventually destroy the kidneys and/or the heart.

## **The Circulatory System**

Dr. Aly cited new scientific findings showing that the walls of capillaries are destroyed by waste products from protein and excessive protein which is stored there. These studies were made by Prof. Lothar Wendt of the University in Frankfurt, Germany. (Unfortunately, these studies are only available in German at this time—a language spoken fluently by Dr. Aly—but hopefully they will be translated for American scientists, doctors, and nutritionists.)

Dr. Aly went into great detail showing how important the circulatory system is for good health, and how the combination of saturated fats and too much animal protein causes many diseases not usually thought of as being directly associated with it. The arteries, veins, and capillaries carry the nutriments and oxygen for all the cells of the body. Every cell is dependent on this circulatory system for its nourishment.

All waste products from the metabolic process are returned to the blood vessels to be eliminated from the body. Thus, good circulation is essential! The walls of the blood vessels need to be elastic, thin, permeable. When excess fats and amino acids are deposited on the walls of the blood vessels, the walls become thick, inelastic, and impermeable.

When the passageways become narrowed, occlusions can occur causing (for example) a coronary of the heart. Another less known effect, however, is the above-mentioned interference with cell metabolism. When the long chains of amino acids from animal protein along with saturated fats catch on the small pores of the walls of the blood vessels—especially the capillaries—the surrounding cells become undernourished.

Normally, the capillary walls should be 300 angstroms thick (an angstrom is a unit equal to 1/100,000,000 of a centimeter). If the walls become thicker, 500 to 1000 angstroms, nutriments and oxygen are unable to get to the cells adequately and waste products cannot get out. Even diseases such as cancer may be caused by this clogging of the vessels as these cells deteriorate and become susceptible to numerous diseases. There is also the theory that the body has to raise the pressure to force the blood through the clogged vessels, in order to get nutriments to the cells. Again, perfect circulation is essential to perfect health!

Dr. Aly feels that a person would be much less likely to get excessive amounts of protein from vegetable sources. Protein in general in the vegetable kingdom is not so highly concentrated as animal protein is, and he views this as a desirable feature rather than undesirable as was formerly thought. The body can make up its proteins provided the essential amino acids are present. He believes in complimentary proteins such as beans and corn, and felt that a vegetarian diet containing a variety of foods is adequate for promoting and maintaining good health. (It is also now known that so-called "complete" proteins are also widespread in the vegetable kingdom, as in most nuts and seeds, and leafy greens. Even "incomplete" proteins may often rank a mere few percentage points lower than an arbitrary dividing line, in one or two of the essential amino acids and thus be stigmatized as theoretically inferior—yet it is quite possible to utilize even such erroneously-classified "incomplete" protein foods as the only

concentrated protein sources, without resorting to combinations at all. -ed.)

Dr. Aly did not feel that protein concentrates as a supplement are necessary in a balanced vegetarian diet.

## **Harmful Effects Of Salt**

Dr. Aly discussed the overuse of salt in the diet and its consequences. Natural sodium is needed in the body only in small quantities, one to five grams. Sodium is found naturally in foods, so one can live well without adding inorganic table salt to food at all. (See: chapter on *Salt Eating* in Dr. Shelton's Vol. 11, chapter on *Salt is Poisonous*, in his Superior Nutrition, and Lesson 29 on eliminating condiments from the diet.)

Table salt (sodium chloride) causes osmotic changes in the blood. The tissues fill with fluids and then must be cleaned out through the kidneys and skin. At Dr. Aly's clinic, he puts his patients on a modified fast, giving them fluids, juices, and water to get rid of the sodium chloride. (He prescribes an alkaline vegetable juice program—e.g. carrot juice—rather than a plain water-fast, as he feels the juice counteracts acidity.) Too much salt overtaxes the kidneys. Regular doctors give their patients diuretics which take fluid and salt away, but are harmful as they also take away essential minerals.

Salt causes more fluid in the blood vessels, and the body tries to force elimination of the fluid to get rid of the salt. The combination of salt, animal protein, and saturated fats—all so typical of the average American diet—forces the blood pressure to rise.

## **Intestinal Flora**

Dr. Aly discussed the importance of the intestinal flora in the lower intestines. *Lactobacillus acidophilus* is necessary in the intestines to help digest, food and to produce vitamins B12 and K.

The intestinal walls serve an important function in acting as "traffic police" to prevent poisons from passing into the body. He felt that allergies are caused by the loss of the flora in the intestines and poisons getting into the blood. He emphasized the beneficial effects of eating raw foods as they have their own enzymes for digestion, and these are destroyed by cooking. That is one reason why *more* food is needed when it is cooked.

He felt that a high-protein diet is not necessary if one has good intestinal flora. He cited the study of New Guineans of Mt. Hagen, who are very healthy people although they eat 15 to 20 grams of vegetable protein a day (compared to current recommendations of 45 to 55 grams for the average adult female and male). Amazingly, these New Guineans put out far more nitrogen than could be accounted for with their meager protein intake. Dr. Aly felt that they must have good flora and are producing their own protein.

Dr. Aly does not recommend such a small amount of protein for most people, as there are so many things in modern society that interfere with good intestinal flora. He felt, for example, that the artificial fertilizers have depleted the trace minerals in the soil, which are therefore deficient in the fruits and vegetables. Organic manure, for example, would be better; and bacteria in the soil would be just as necessary as in the intestines. He also felt that pesticides, artificial colorings, etc., are all carcinogenic, allergenic, and harmful to the health although they make things look good and sell better. He believes that additives destroy the natural intestinal flora.

Regarding vitamin pills, his view is that they contain what scientists know, but not what has not yet been discovered; and that the natural fruits and vegetables in a fresh state and organically grown if possible, are more desirable. He recommended that a strict total-vegetarian (using no dairy foods or eggs) eat three to five grams of parsley every day, as it helps the intestinal flora (which in turn produce vitamin B2).

## **Superiority Of Natural Unrefined Foods**

Dr. Aly went into great detail regarding the superiority of natural unrefined foods. He cited studies by Prof. Burkitt, and the English studies by Cleave and Campbell, the Saccharine Diseases, which state that most diseases arise from abuse of refined products. They say that essentially the diseases are different symptoms of the same problem.

Dr. Aly demonstrated what occurs through the refining of a grain of wheat, for example. This takes away the vitamin E, essential fatty acids, trace minerals, the wheat germ, and an essence that scientists do not as yet know about. What remains is mainly carbohydrate. He asserted that scientists know about elements, but they do not know about the essence of life itself. Putting a few of the known synthesized vitamins back into the refined flour cannot make it equal to the original whole grain. Although scientists could even copy the wheat grain exactly as they know its component parts, it still would not grow. Yet grains found in tombs 4000 years old will still grow. There is a life essence locked in, which scientists do not know how to reproduce. That essence is destroyed by refining. (He added that grains can be stored in dry tins if kept cold and dark, but they will not store well after they are ground.)

## **Nutritional Disaster Of Refined Sugar**

Dr. Aly was adamant that if white sugar were banned, everyone's health would improve. He explained, that there is a constant blood sugar level of 80mg in the blood, needed for muscles and organs. When white sugar is eaten and gets into the blood, it gives a high blood-sugar level of 150 to 200. Low blood sugar is bad—no energy—but the body has no use for high blood sugar either. The body takes it and stores it as fat. If an apple or an orange or an unrefined carbohydrate is eaten, it takes a longer time to get the sugar and energy; thus there is a normal rise in the blood sugar level. When refined sugar is eaten, it gets into the blood stream quickly, and the blood sugar level becomes too high; insulin is then secreted to break down the sugar and store it in the body as glycogen. Then the blood sugar drops below normal level, and there is a feeling of a lack of energy.

If a lot of refined sugar is eaten, the pancreas is overworked. People who eat refined sugars for "quick energy" are taxing their systems and not really getting lasting energy, because the body will over-react and drop the blood sugar level below normal, and they will then have less energy than before. Unrefined carbohydrates will provide an even, long-term energy level, and not the "yo-yo" effect of extreme high followed by extreme low.

Although honey, maple syrup, blackstrap molasses, dates and other dried fruits are in varying degrees better than white sugar as they have other nutriments, they too will cause high blood sugar if too much is eaten, as they are highly concentrated though not refined. (It is often recommended to soak dried fruit in pure water overnight, to reconstitute it in fluid content and reduce the sugar concentration, -ed.) He also felt that too much of fruit juices would not be good as the sugar gets into the bloodstream too quickly, and that it would be better to eat fresh fruit.

In summing up, the best diet for good health would be a balanced vegetarian diet containing a variety of (if possible) organically-grown fresh fruits and vegetables, whole grains, nuts and seeds, and dairy products if desired.

Reprinted from the *Vegetarian Voice*, September/October and November/December 1976.

## **Article #12: What's Wrong With Your T-Bone Steak? by Alvin E. Adams, M.D.**

Flesh food in the diet is an important cause of disease and death among humans. Meat, Fish and poultry transmit bacterial and parasitic infections to man. Pesticides, antibiotics, and hormones find access to our bodies through the meat we eat. Also, flesh foods, by their very nature, are harmful to human health because of the effects that cholesterol, animal fat, blood, and lack of fiber have on various body systems.

### **Meat Lacks Fiber**

Flesh foods lack natural fiber found so abundantly in whole grains, fruits, and vegetables. Fiber is composed of cellulose. It is indigestible and therefore adds bulk and moisture to the stool. A high meat diet is low in residue-containing foods resulting in constipation with hard and infrequent stools. This in turn often results in the development of hemorrhoids.

Straining and increased tension in the smooth muscle of the colon wall are thought to be the cause of diverticulosis. The pouches of diverticulosis often become impacted with fecal material and may become infected resulting in abdominal pain. Diverticuli occasionally perforate or hemorrhage, requiring emergency surgery.

### **Meat Is Suspect In Cancer**

Meat in the diet is now suspected by many scientists to be a major cause of cancer of the colon. With a high meat diet the transit time of food through the gastrointestinal system is prolonged. Waste matter which should be eliminated promptly remains in contact with the rectal tissue for long periods of time. Cancer-causing compounds may be formed by chemical reactions or as byproducts of bacterial metabolism. These chemicals may initiate cancer in the colon wall. Cancer is the number two killer in the U.S., and colon cancer is the most common cause of cancer deaths. Seventy-five percent of all colon cancers occur within the last six inches of the colon where feces are stored.

### **Meat Is High In Saturated Fats**

The fat found in dairy products and all animals except fish is highly saturated. Saturated fats in the diet tend to raise the blood cholesterol and accelerate the development of hardening of the arteries by the process of arteriosclerosis. Wherever an artery becomes completely clogged because of this pathologic process, a disaster occurs in the tissue beyond the point of obstruction. A blocked cerebral artery results in a stroke, an obstructed artery in a leg may lead to gangrene, and an obstructed coronary artery results in a heart attack. Heart attacks and strokes are the number one and number three killers in this country but are only minor causes of death in countries where there is little or no meat in the diet.

### **Blood In Meat Can Be Harmful**

The blood remaining in meat can be a source of potentially harmful compounds. The blood is the vehicle which carries waste products from the site of their formation to the organ of elimination or metabolism. The bloodstream carries carbon dioxide to the lungs for removal from the system, and it carries other waste products such as urea, uric acid, and creatine to the kidneys for elimination from the body. The blood, also, distributes hormones from the site of production to target organs. Blood in the meat you eat contains the waste products of the slaughtered animal. The removal or metabolism of these chemicals places an extra work load on your liver and kidneys. If the animal was in a state of excitement or fear when it was slaughtered, animal adrenalin and other hormones never reach their target organs but remain in the meat only to have an effect upon you as you eat your blood rare steak.

## **Meat Contains Pesticides**

Many pesticides are fat soluble chemical compounds which are accumulated and stored in animal fat. After eating feed sprayed with pesticides, surprisingly high levels of these complex hydrocarbons are found concentrated in choice-cuts of meat. It has been estimated that 80% of the pesticides which find their way into the human diet come from the meat we eat.

## **Meat Has Hormones**

Hormones and antibodies administered to animals to force growth and prevent disease are metabolized fairly rapidly by the animal. Frequently, however, animals are slaughtered before the drugs have been cleared from the animals' systems, and humans are exposed unnecessarily to these compounds. Until recently, D.E.S. (Diethylstilbestrol) was mixed with feed to promote rapid growth and development in animals. Women who have taken this drug during pregnancy are likely to have boys who are sterile or girls who are susceptible to genital tract cancer. Residues of D.E.S. were frequently found in meat while its use was authorized by the F.D.A.

## **Meat Has Bacteria And Parasites**

Outbreaks of Staphylococcal Enteritis, Shigella Dysentery, and Salmonella often have been traced to meat dishes improperly prepared or preserved. Oysters and shellfish taken from waters contaminated with human waste are a significant cause of Infectious Hepatitis.

Parasitic infections frequently are traced to a flesh food diet. Tapeworms are found in beef, pork and fish. Tapeworm infestations result in chronic disability, weakness, and anemia. Trichinosis is the most important parasitic disease transported by meat in the U.S. THIS COUNTRY HAS THE DUBIOUS DISTINCTION OF LEADING THE WORLD IN TRICHINOSIS. We have approximately three times as much trichinosis as all the rest of the world. About 16% of all adults in the U.S. are found to have trichinosis at autopsy. A heavy infection of trichinosis may cause death, but more often the only manifestations of trichinosis are chronic aches and pains which usually are passed off as a rheumatism or arthritis. Unfortunately, there is NO CURE for trichinosis.

Proper cooking can kill the parasites and bacteria found in meat but when meat, poultry, and seafood are eaten raw or only have a brief exposure to heat, one is inviting bacterial or parasitic disease.

## **Good Health Requires Effort**

If flesh foods were eliminated from the diet, there would be a significant decrease in the disease, disability, and death which result from the conditions that have been discussed herein. Good health is not an accident; it must be pursued with diligent effort. It results from adhering to a healthful diet, avoiding all that is harmful to health and using moderately those things which promote it. Eliminating or reducing flesh foods from the diet is a step toward better health.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #13: Fishitarian Or Vegetarian? The Difference Might Be Fatal! by Bob Pinkus

## **Article #13: Fishitarian Or Vegetarian? The Difference Might Be Fatal! by Bob Pinkus**

A lot of people are becoming vegetarians these days. For a great many people the world food crisis

provides sufficient motivation to change from carnivorous livestock-based diets to vegetarian diets. Some of those so motivated have contended that a diet which includes fish would be a smaller strain on the resources of the land to produce food for our planet's large human population. This statement overlooks the fact that fish use plankton of plant origin as a primary food at the low level of the food chain. A plankton cultivation system arising from a future technology would be a much more efficient method of producing food for earth's people than eating fish which are much higher on the food chain than plankton.

Plankton cultivation of course would require the development of a technology which did not remove this key planetary input from its role as an oxygen provider. Much of the world's oxygen is provided by plankton. A plankton cultivation system could be developed without too much effort if it became necessary. To date it is not. The produce of the land if eaten directly can today supply more than enough food for all of the planet's human inhabitants. We now have available about one acre of arable land per person on which to produce food for everyone now living. A vegetarian diet requires about half an acre per person; and half of that will provide a total vegetarian or "vegan" diet.

Jacques Cousteau has been quoted as saying that *some 40% of the life in the seas has died in recent decades*. Pollution has been a major factor in this devastation. So has so-called "overfishing" of the world's waters. To the fish which is caught, any fishing is "overfishing." The massive scale of modern fishing has led to a great increase over time in fish yields up until recent years. A few short years ago a decline in yields was noted even though fishing was being attempted on an even grander scale. Clearly the fish population is being decimated by fishing. Massive fish kills caused by pollution have also been reported in recent years around the world. Like other animals fish concentrate environmental pollutants the higher one goes up the food chain. Recently fishing the Hudson River was banned because of the presence of PolyChlorinated Biphenyls (PCBs) in fish at levels up to 350 parts per million. FDA surveys of grocery store foods in 1972 had shown PCBs to be present at levels up to 35 parts per million in fish. A 35 part per million level constitutes 7 times the level of PCBs which sterilized mink whose diets included Lake Michigan Coho Salmon. Lake Michigan residents were warned not to consume more salmon. The PCB dietary levels of the mink were determined to have been 5 parts per million. That level caused complete reproductive failure in the mink. The mink ranchers have since switched to other foods for the mink. The presence of 70 times the 5 part per million level in Hudson River fish was blamed on General Electric which had been dumping the industrial chemical in the river for years. Widely used in industry, PCBs have also entered the environment through the burning of containers in which they have been used.

PCBs are used in plasticizers, adhesives, sealants, transformers, and a wide variety of industrial applications. A 1973 study by scientists at the Davis Campus of the University of California reported that PCBs were the environmental derivative of DDT degrading in the environment. Recognition of PCBs in walrus, seals and polar bears at the Arctic Circle had prompted the research of the Davis scientists. The Arctic Circle is thousands of miles from the nearest industrial application of PCBs. DDT has been used worldwide. Spread by wind and water, DDT is estimated to be present in every human being. The Davis team reported that the interaction of time, about four years, and sunlight causes DDT to break down becoming PCBs. Half the American population is estimated to have measurable amounts of PCBs. Concentrated up the food chain via fish and other animal products, PCBs like other pollutants, reach the consumers of these products in high levels. Fish kills caused by PCBs have been reported around the world. PCBs at low levels have also caused mutations in plankton.

A sampling of massive fish kills from various sources of pollution in recent years would paint a picture somewhat like this:

June 1968, 100,000 fish in the Stanislaus River in California including carp, catfish, sturgeon, striped bass, sunfish, shad, smallmouth black bass, hardheads, blue-gills are found dead in the river. The California State Fish and Game Department calls the fish kill the result of pollution.

August 12, 1968, a number called significant by the Virginia State Water Control Board is reported in

fish killed in the James River because of toxic human-made chemicals introduced into the water.

August 29, 1968, 1,000 small fish of different species are found dead in Accabonac Harbor at Riverhead, Long Island, New York.

## **Pesticides Spray**

The New York State Bureau of Marine Fisheries calls pesticide spraying the cause of the fish kill.

Scuba divers off Sea Bright, New Jersey, in the spring of 1969, report a graveyard of crustaceans and fish at depths of less than 100 feet. Cunner, black sea bass, ocean pout, rock crabs, tautog, lobsters, mussels are among those found dead. Great migrations of fish and crustaceans away from the region are reported by other divers. A low level of dissolved oxygen in the water is estimated to be the cause of death.

The Rhine River in West Germany and Holland in June of 1969 is the site of a fish kill of perhaps 40 million fish. Endosulfan, a chlorinated cyclic hydrocarbon marketed by the Hoechst chemical firm as Thiodan, is the cause of the kill.

May 5, 1970: 349,000 plus fish die in Missouri's Crooked Creek after a large quantity of toxic material is dumped into the water. Clordane and Malathion in Xylene is blamed for the kill. Ninety percent of the dead fish are orange throat divers and minnows. All other aquatic life in the stream is killed for a distance of two miles from the dumping. Snakes, turtles, tadpoles, crayfish and large numbers of frogs are among those killed.

December 18, 1970: millions of fish wash ashore dead off the Peruvian coast of Pisco. A thick layer of dead fish 15 feet wide is formed stretching nearly two miles. Flounders, "cabrillas" rays, "corvinillas," ayanques, and "pintadillas" are among those killed. Toxic sewage is a suspected cause of the kill.

May 30, 1971: Large numbers of dying fish drift ashore between Jubail and Ras Tanura on the Saudi Arabian Persian Gulf. Hamoor, black sbaitee, and angel fish are among those killed. Large mature adults weighing from one to 10 pounds with some up to 20 pounds are the principal victims of the kill. A large octopus and a large barracuda are also found killed. The cause of the kill is not discovered to date. All of the fish have grossly inflated air-bladders. The network of blood vessels in the airbladder's dorsal wall is enormously distended and filled with blood. All the fish have empty stomachs but were fat and seemed normal.

August 5, 1971: Lees River, Massachusetts is the site of a fish kill involving nine species of marine fish and two species of invertebrates. Over one million juvenile menhaden are killed. Lesser numbers of weakfish, cunner, American eel, tautog, oyster toad fish, white perch, silver-side and mummichog also die. Half a million prawns are killed. A depressed level of dissolved oxygen is blamed on industrial and commercial discharges. Excessive nitrogen, phosphorus and ammonia are found.

Metropolitan New York: Fish "caught" off the New York gap, the site of sewage dumping for large parts of the Metropolitan area, are being brought on board ship decks and breaking up on the decks. As a result the fish are being sold fillet rather than whole. The situation continues to date.

Clearly the dangers involved in eating fish ought to be reason enough to be truly vegetarian. The tragic case of the many Japanese children born deformed because polluted fish were eaten by the parents (of the Minamata, Japan children) is one which may be repeated more often as people continue to eat animals from the sea. Mercury is blamed for pollution of the fish in that case.

The fact that PCBs have been found to produce cancer as well as sterility, disfigurement, liver problems, and other horrors, ought to prompt officials to ban fish containing PCBs under the provisions of the Delaney Amendment. The Delaney clause states that chemicals found to cause cancer cannot be present in foods. If PCBs cannot be removed from "foods," those containing PCBs should be banned from human consumption.

What of the ethical side of the question? Dolphins face extinction because modern tuna fishing catches and kills large numbers of them each year. We should be concerned about the tuna also. Each tuna is a living creature with a right to live. To a fish being caught the concept of "endangered species" is immediately reduced to one of "endangered individual." Can we relate as well to fish as we do to land animals? As vegetarians we can see that land animals move, breathe, feel, think, live. Do we not also realize that fish do all of this too? Perhaps a few days in a so-called "seafood" restaurant might convince one that the bodies of the fish being consumed are indeed bodies of once living, breathing, thinking, feeling animals who happened to live in water. In Taiwan live puppies are found in cages as one enters a restaurant. One can then select the dog to be killed for one's meal. The "chow dog" of old China is the original reason why chow mein has its name. In America and elsewhere in the world one can find live lobsters similarly displayed ready for murder, in the midst of restaurants. Aren't both acts equally horrible?

We can look too, to the meaning of the word "vegetarian;" it is derived from the Latin *vegetas*—full of life! Clearly if we fill our bodies with the bodies of murdered fish we are full of death instead of life.

Fishitarian or vegetarian, which will it be? The choice belongs to us. The victims cannot vote. In a sense though we are all victims of the fish-eating habit whether we eat fish ourselves or others do. The continued fishing of the world's waters may result in a disturbance of the already fragile eco-system of the waterlife of earth.

That fish and plankton are interdependent ought to be clear. Fish feed on plankton. Fish wastes and decayed fish become a basis for plankton nourishment. There is a symbiotic system among plants and animals in water just as there is on land. Plankton produce oxygen which is used by all life on earth. With increasing fishing removing fish from the waters of the world plankton may become a vanishing species. Without plankton earth would be deprived of vast amounts of oxygen. Without that oxygen it is likely that planetary extinction for all forms of life would follow. The continued plunder of earth's waterways for fish is senseless and dangerous. Whether we remove animals at the top of the ocean food chain like whales or animals near the bottom of the food chain like krill which are a fish type of plankton, we are dangerously jeopardizing the planet's ecosystem. Krill has been looked upon by some as a potential new food for people. Hundreds of millions of tons of krill may soon be "harvested" annually for human consumption. That these fish plankton are interlocked with plant plankton which produce oxygen should be clear. Removing them may endanger the continued existence of the plant plankton they have interplay with.

Even those who do not consume fish directly may be consuming them indirectly. Fish are now a major source of animal feed in America and other parts of the world. The use of animals and animal products as food actually involves the indirect consumption of many fish. Fish oils are also often used as a source of the Vitamin D added to milk. Some dairies use irradiated ergosterol, also called viosterol, as a vegetarian source of Vitamin D, but switch to fish oils as price dictates.

Conscience then dictates abstinence from animals and animal products in one's diet. As a first step in one's vegetarianism the elimination of *all flesh* as food is a good move. Fish, like other animals, belong in their native environment and not in our stomachs. As we are what we eat, if we do not eat corpses we are less likely to become corpses quickly ourselves.

Fishitarian or Vegetarian? Hopefully a wise choice to be vegetarian will be made by all of us.

## **Article #14: The Facts About Vitamin B12 by Robin Hur**

Vitamin B12 is an essential nutrient; it is involved in the production of red blood cells and in the utilization of nervous system-dependent carbohydrates. The inability to absorb B12 leads to so-called "pernicious anemia" in which abnormal red cells are formed, while a lack of B12 in the diet raises the risk of damage to nerves of the spinal cord. Inasmuch as nutritionists report that there is little, if any, of the vitamin in plant foods it behooves strict vegetarians to assure themselves of adequate supplies of B12.

A Mt. Sinai researcher suggests adults need about 0.1 microgram of B12 per day. However, this recommendation is based on observations of individuals taking conventional diets. Normal diets contain gross excesses of fat, protein and refined foods, all of which tend to elevate needs for B12.

Indian researchers found that high-fat intake causes marked B12 deficiency in laboratory animals fed normal amounts of the vitamin; saturated fats, in which beef, eggs and dairy products are extremely high, had an especially severe effect. High protein diets tend to deplete the vitamin in the blood, liver and kidneys of laboratory animals; animal proteins evidently produce more rapid losses than plant proteins. A diet dominated by refined foods more than doubled the B12 needs of baboons. Diets high in animal products, fat and refined carbohydrates lead to conditions in which absorption of B12 is inhibited in humans also.

It appears adults taking low fat, whole food vegan diets should need no more than 0.05 micrograms of B12 daily. The National Research Council recommends adults take 100 times that amount, or 5 micrograms per day. With consistent inconsistency they recommend 1.0 microgram of B12 per day for infants, which is a high multiple of what breast-fed tots get.

It's not altogether clear that nonsmoking vegans need any B12 as such in their diets. The vitamin is normally synthesized by bacteria in the lower regions of the digestive tract and nonsmoking vegans evidently develop the capacity to absorb adequate amounts of their bacterial supplies. British researchers report that only one nonsmoking vegan is known to have suffered from "manifest symptoms and signs" of B12 deficiency. On the other hand, the serum B12 levels of British vegans tend to be very low during their first few years on a vegan regime. And as long as serum levels remain low the possibility of neurological damage persists.

There are several ways in which vegans can protect themselves against declining amounts of B12 in their blood and elsewhere. They could of course take supplements, but supplemental B12 should not be necessary if the diet itself is a sound one. To this end vegans should avoid high levels of fat and protein and avoid tobacco and refined foods. These moves will keep B12 needs down and facilitate synthesis and absorption of the vitamin. As added precautions vegans can include good sources of cobalt and/or B12 itself in their diets.

Each molecule of Vitamin B12 contains a molecule of cobalt so the diet must include a source of cobalt if the intestinal flora are to synthesize the vitamin. Seaweeds are incredibly rich in cobalt: the amount of kelp it takes to flavor a single bowl of salad contains enough cobalt to synthesize a year's supply of B12. And there is growing evidence that raising cobalt intake raises the body's supplies of B12.

The serum B12 levels of rabbits rise when they are fed inorganic cobalt or hay and oats grown in soil containing normal amounts of cobalt. Hamsters fed inorganic cobalt and no B12 had relatively high tissue levels of B12 and seemed to be obtaining entirely adequate amounts of the vitamin.

The Cal-Berkeley researchers who conducted the hamster study reported their result to be "a new finding among the nonruminants." Prior to this finding, though, a Russian researcher had reported that the combination of iron, vitamin C and cobalt had a positive effect on B12 deficiency in humans.

Vegans who want to get their B12 ready-made need look no further than their gardens. An ounce of the roots of leeks, beets, and other vegetables would provide .1 to .3 micrograms of B12 which is more than a day's needs. By eating vegetables right out of the garden one inevitably takes in a little soil and healthy soil contains healthy amounts of B12.

When livestock are taken from open areas and put in feedlots, broiler "hotels," and hog "factories," the animals must be given supplemental B12 to compensate for their inability to nose (or beak) around the soil. All foods in the wild tend to pick up B12-bearing soil and micro-organisms. South African researchers discovered bats that live exclusively on fruit need as much of B12 as humans. The "fruit bats" get plenty of B12 when living in the wild but when brought into captivity and fed store-bought fruits they developed severe B12 deficiency.

Seaweed contains not only enormous amounts of cobalt, but rather substantial amounts of B12 itself. Concentrations vary widely, however, ranging from 0.004 micro-grams per gram for kelp to 0.6 micrograms per gram for *calothrix parientina*. Two ounces of the latter would provide an adult with a whole year's supply of B12. It would require about a third of an ounce of kelp per day to obtain all one's B12 needs in the form of active B12 from kelp. In view of the large amount of cobalt in kelp, though, vegans should need no more than sprinkling amounts of that (or any other) seaweed.

Seaweeds are actually species of algae. Other algae, including the "moss" that grows on the north sides of trees and the "scum" that builds up in ponds, are also good sources of B12. Algae from Lake Chad is dried into B12-rich cakes which have a taste and texture not unlike cheese. You can get a week's supply of B12 from the water you take in while swimming in a fresh water pond or an unchlorinated swimming pool.

Greens and sprouts offer the broadest possible array of vitamins and minerals: if grown in soil rich in cobalt and iodine they are apt to provide everything the body needs except a source of energy. Vegans who raise their own food can assure themselves of adequate intakes of iodine and cobalt by enriching their soil with seaweed. Those who rely on store-bought foods can include a little seaweed in their diets. Both groups can boost their B12 intakes by eating, rather than discarding, the stringy roots of common vegetables and eating in the wild. AH vegetarians should avoid tobacco and refined foods and keep fat and protein intakes down; these moves will lower B12 needs, enhance absorption of the vitamin and insure the individual good health.

There are reports that greens and sprouts contain active B12. Comfrey was said to be a rather good source of the vitamin but British researchers claim they found no B12 in comfrey. Meanwhile, we have plenty of known sources of the vitamin in our gardens, forests, ponds, lakes and oceans. We need only reunite ourselves with our natural surroundings to abound in what our bodies need.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #15: Wolf! Wolf! by V.V. Vetrano, B.S., D.C.

### **Article #15: Wolf! Wolf! by V.V. Vetrano, B.S., D.C.**

Wolf! Wolf! cry the media. Then everybody runs as fast as they can, including *Hygienists* and some *Hygienic doctors*.

There were too many people becoming vegetarians, so something had to be done to scare them away from this healthful and unprofitable practice. The animal-exploiting industry was probably behind the study which was done on the Vegans in England, and other studies that were done here in America and elsewhere.

Hygienists, vegetarians, and Vegans are all in a dither because of the newspaper stories in the regular media about the dire consequences of a strict vegetarian diet. Some are buying dulse. Some are eating brewer's yeast; some are taking vitamin B12 supplements; and some are eating meat, cheese and eggs again because they are actually afraid.

Why should they be afraid? I'm not the least bit afraid. Our principles are either right or wrong. They have worked for *Hygienists* for over a hundred years, so how can they be wrong? I've seen these principles properly applied successfully over and over again in pernicious anemia and other so-called "deficiency" diseases and I know for sure it is not the principles that are wrong.

We are going to devote much of this issue of the *Review* to exposing the vitamin B12 hoax. It must be done because unfortunately people will allow themselves to be tossed about like houses in a tornado instead of realizing that *Hygienic* principles are *not* wrong.

When the vitamin B12 scare occurred and the media kept telling us we couldn't get our vitamin B12 from the diet to which we are anatomically and physiologically adapted, I immediately suspected something. To myself, I said: "If we can't get vitamin B12 from our foods, or if bacteria cannot manufacture it in our intestinal tracts, then everything we are fighting for and everything we believe in is untrue. If we have to go out and become a coprophagous (manure-eating) animal and eat inadequately washed vegetables to secure our vitamin B12, then *Hygiene* as a science is invalid. We are either frugivores or we are not."

Since numerous scientists for the past 200 years have shown us that we are primates, and that fruits, vegetables and nuts are the proper foods for people, then the fault lies elsewhere.

Dr. Shelton is not able to keep everybody in line because he is busy writing a book. He has not been keeping up to date on some modern issues.

Somebody has to help prevent people from being scared by the wolf call every time the medical profession, the meat packing industry, and the purveyors of so-called health foods cry "wolf!" So I'm going to do it.

For all those who will listen, I'm going to do my best to uphold the principles of *Natural Hygiene* in the future. This does not mean that our growth will be stifled as some claim simply because we stick to *Hygienic* principles. To insult *Hygienic* principles merely because they were discovered years ago is as foolish as casting aside Newton's Law of Gravity because it was discovered years ago. The passage of time does not invalidate truth. We are going to look for the real cause of the problem and place the responsibility where it really belongs. We will get rid of causes instead of palliating symptoms with supplements.

For those people who are in doubt about *Hygienic* principles, I suggest that you study *Hygiene* more thoroughly. If it is wrong in this one instance then the whole system is wrong—and the whole system is *not* wrong.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #16: The Vitamin B12 Hoax by V.V. Vetrano, B.S., D.C.

### **Article #16: The Vitamin B12 Hoax by V.V. Vetrano, B.S., D.C.**

The medical profession is screaming "wolf" and we are foolishly falling for it. Physicians are constantly bombarding the country with articles telling vegetarians that they must eat animal products such as meat, fish, eggs, or milk and cheese in order to make a sufficient amount of vitamin B12. They are grouping all vegetarians together and not discriminating at all. Just because there may be some sick vegetarians who cannot absorb vitamin B12 (and this is questioned by eminent scientists), it does not follow that all

vegetarians cannot absorb this vitamin. Most people who have turned to vegetarianism were sick to begin with and this sickness is the reason they changed their diets. Most of them willingly state they have been healthier since changing than ever before in their lives. One or two vegetarians may seem to be a little low in Vitamin B12 but this does not mean that all strict vegetarians are, or ever will be.

I'm surprised that *Hygienists* are falling for the propaganda that is purposely put out to scare people away from becoming vegetarians. It is a scientific fact that we are frugivores and the frugivorous diet has been well established scientifically. We know the *Hygienic* diet of fruits, nuts, and vegetables is the diet that we are supposed to live on. We will be well-nourished and more healthy if we eat only those foods to which we are constitutionally adapted.

There are so few people who live strict *Hygienic* lives that I can't say that anyone has superior health at the present time and in the present polluted environment. Simply because in our present polluted environment, where people are forced to overwork, very few people are living *Hygienically* does not mean that people *cannot* live *Hygienically*, and the fact that one or two Vegans (not *Hygienic*-Vegans) may be low in vitamin B12 does not mean that a strict *Hygienist*, living correctly in all other aspects, will lack vitamin B12.

Here is another thought: Nature puts very little vitamin B12 in foods meant for people. This should tell us something. If she put very little of this vitamin in food, it must mean that either we don't need very much, or that we must rely on bacteria to form it for us. Also, who can say how much of this vitamin is necessary? According to medical sources only one microgram a day is adequate to "cure" pernicious anemia, so the minimum requirement has been set at this level. We may not need even this much. Just because some scientists took a group of conventional people on an omnivorous diet and determined the amount of vitamin B12 in their systems, averaged that, and came up with a figure, one cannot conclude that this is the amount of B12 necessary for normal healthy *Hygienists*, vegetarians, and Vegans. How many times has Dr. Shelton pointed out to us that taking the averages of anything from a group of sick people means nothing? Why should an average of B12 in a lot of people eating haphazardly and gorging daily on gore, guts and garbage made of animal bodies and their secretions, scare us to death? Have we no faith in the living organism? Have we no faith in the natural scheme of things? Are we forever going to let ourselves be blown hither and thither like a feather in the wind by every two bit scientist that comes along? Have we no faith in the principles of *Hygiene*? We should be standing firm like a mighty oak with our roots deeply planted into the solid foundation of *Hygiene* that Dr. Shelton structured so well for us. Instead, we are a group of wishy-washy people, frightened to death about one case of a vegetarian lacking vitamin B12. The papers capitalized on this one case to scare people into the meat markets and vitamin shops.

I've fasted numerous cases of people with pernicious anemia who have recovered their health by turning to *Hygiene*. I've never seen a *Hygienist* who had pernicious anemia. The flesh eaters supposedly secure plenty of vitamin B12. Why do *they* develop pernicious anemia? They are overloaded with vitamin B12. Why couldn't they recover under medical care? They had had vitamin B12 shots, liver extract, and vitamin pills. Why did it not cure them? I'll tell you why. Simply because life and health are more than one vitamin. Life is more than two vitamins. Life and health depend on a myriad of reactions and inter-reactions of materials and influences, not just one. Supplying just one element of the physiological needs of the body won't produce superior health. It may mask symptoms sufficiently for a while to fool the physicians with the scientific minds, who believe in specific cures for specific diseases, but it never fools Nature.

We are in a world that is rapidly deteriorating. We are turning out children who are sickly and who have very little vitality. Because of the environmental pollution, they are sometimes lacking in digestive enzymes as well as one or more enzymes or hormones that are absolutely essential for health and sometimes life. You can't blame *Hygiene* for this deterioration. The fault lies not in *Hygiene*, whose principles are eternally true, but in our wrong way of living and our polluted environment. How quick we are to point the finger at *Hygiene* and say; "It's lacking. It must be changed. We must go forward. *Hygiene* must not be stifled." I do not call sticking to basic principles being stifled. If someone feels he

or she is dusting antiques when upholding the principles of *Natural Hygiene* then he or she doesn't understand *Hygiene*, or he or she is looking for ways to compromise.

Instead of looking for the reasons why *Hygiene* may not appear to be valid, people immediately condemn *Hygiene* and revert back to their dirty, disease-producing omnivorous diet.

Instead of trying to prove the validity of the science of *Hygiene*, modern *Hygienists* seem to be busily engaged in trying to disprove it. With so little faith, how can we expect to grow?

Just because pollution in our environment from cars, nuclear plants, power plants, microwave stations, etc. causes some people to be born with deficiencies so they are unable to digest, absorb or utilize vitamin B12, one cannot infer that every vegetarian has this defect. Therefore, it is not true that every vegetarian needs to eat some dairy products in order to have sufficient B12.

Some *Hygienists* may complain that they don't have the discipline to live *Hygienically* in an un*Hygienic* environment. If they develop anemia, one cannot say that *Hygiene* is at fault; if *Hygienic* principles are violated, the individual must suffer. In addition we must not overlook the fact that some people say they are living *Hygienically* when they are not. We must delve deeply into their life history to see whether or not they are truly carrying out a *Hygienic* life. Nine times out of ten they are not.

Why do people with pernicious anemia recover their health when coming to the Health School? Simply because the cause of the anemia is removed and the conditions of health are supplied and the body heals itself. Why haven't those supposed Vegans who developed vitamin B12 deficiency come for real *Hygienic* care instead of listening to researchers who are subsidized by the meat packing industry? Why do they think they have to take shots of vitamin B12 and resort to eating dessicated liver? Why do those who guide them assume they cannot, recover? Have they not thought of living completely *Hygienically*? Why do they not fast to see what the body can do before they fall prey to the vendors of medications and drugs? One reason is because they have been frightened to death and led astray by the vendors of palliatives.

I fasted one woman who had pernicious anemia and who was taking vitamin B12 and iron shots once a month. She was very sick before coming to the Health School but she recovered, not only from that trouble but from several other problems, at the same time. Why? Because disease is a unity and people don't have just one disease. When a person is toxic the whole organism begins to deteriorate, and piecemeal treatment to hide symptoms is not satisfactory. Nothing short of total *Hygienic* care will suffice.

Let us not forget that Dr. William Howard Hay recorded 101 cases of pernicious anemia and only eight of those cases failed to recover—and these people were dying when they arrived for his care. Although these cases were recorded fifty to seventy-five years ago, we cannot ignore them. This date points out to me that there are changing conditions in our environment. Instead of condemning and questioning the science of *Hygiene*, as so many people are doing today, we should be seeking the true cause of the increase in cases of pernicious anemia, if there be such an increase.

I've been warning people since 1953 that our environment is lethal and if we don't do something we won't have a race left. Cleaning up our environment is almost more important, at this stage of the game, than *Hygiene*. The world is analogous to the body when given a dose of medicine (poison). An emergency situation has arisen and all bodily processes must be stopped for the more immediate emergency of getting the poison out of the system. Likewise, our Earth is rapidly becoming so poisoned that emergency measures must be taken before we are all killed. The race is deteriorating so fast that it is frightening. We've got to spread *Hygiene* on every front before much more deterioration takes place or it may be irreversible.

It is well known that the past few generations have abused their stomachs terribly. Each generation has been sicker than the last. When people become sick they begin the *Hygienic* diet without first fasting or permitting the body to heal itself. Consequently if they develop a deficiency because of impaired digestion the deficiency is attributed to the vegetarian diet. Actually the deficiency is due to the abuse

given the body before becoming a *Hygienist*. We know that sick people who have been on vitamin B12 injections for years, without much benefit, can take a fast and get well. This recovery would indicate that they still had the power to secrete the intrinsic factor. It also indicates that possibly these people were suffering with a simple gastritis and that after fasting, their inflammatory condition healed, leaving them better able to secrete the necessary enzymes for good digestion, absorption and utilization. It is a fact the anemic get well while fasting and stay well if they continue to live properly. Why they get well is due to a number of factors. The blood picture improves while fasting, though no extraneous vitamin B12 is available. Let those screaming "deficiency" explain that.

The elimination of the toxic factor while fasting is extremely important for recovery of health. Removing toxemia, which is a great inhibiting influence on both digestion and the blood-forming organs is the prime factor in recovery. Toxemia causes lowered functioning power, not only of the secreting glands of the stomach but of every organ in the body, including the blood-forming organs. Lowered functioning power of the entire gastrointestinal system hinders digestion, and causes much fermentation and putrefaction. This in turn interferes with digestion and absorption of nutriment necessary for the production of blood, and also causes the absorption of toxic products of indigestion, producing more toxemia which in turn causes even less functioning and blood-forming power. Good digestion is necessary to remove the protein with which it is combined away from vitamin B12 so it can be combined with intrinsic factor for normal absorption.

Vitamin B12 is necessary in miniscule amounts. It is needed in such small amounts it is spoken of in micrograms, not even in milligrams. Regardless of what authorities say, this much we can secure through the *Hygienic* diet of fruits, nuts and vegetables. When people like Adele Davis, in *Let's Get Well*, say that strict vegetarians who eat no animal foods should take 50 micrograms of vitamin B12 each week "while their stomach secretions are still normal," they are unduly scaring some vegetarians.

Experiments reported in *Gastroenterology* in 1962 lead to the belief that laboratory rats on a diet deficient in iron soon "lost their ability to absorb vitamin B12." This points out the totality of diet. Deficiencies seldom come single. There are many people with gastrointestinal problems who simply don't absorb any of their food properly. These may be lacking in vitamin B12. Again, we see that it is not the *System* that is wrong, but the person. Correction must be aimed at the cause of the problem, not at the modifying *Hygiene*. If we modified *Hygiene* every-time someone got sick, there would soon be no *Hygiene* left and we would all be back in the treating business. We don't change the *Hygienic system* or tell everyone who is eating *Hygienically* to take vitamin B12 just because there is someone who is sick and can't absorb vitamin B12 temporarily. Just because there are a few individuals, not even **Hygienists**, who can't absorb vitamin B12 it does not follow that everyone has to resort to taking vitamin B12 tablets or to eating yeast, or animal foods. Just because some vegetarians develop gastroenteritis from wrong ways of living, does not mean that they all do. We don't change the entire *Hygienic* system and diet any other time just because some people are temporarily unable to digest certain foods. We permit them to recover their health and then they are able to take all the foods that are *Hygienic*. In short, we aim at restoring the sick person to health so he or she can function properly in the future.

Most sources state that vegetable products show no "measurable activity" when speaking of vitamin B12 or cobalamin. "No measurable activity" does not mean that there is no vitamin B12 at all in vegetables. Best and Taylor state that: "The extrinsic factor (vitamin B12) is present in liver, beef, rice polishings, yeast and other substances rich in the vitamin B complex." They continue that: "It is also found in the intestinal contents of normal persons, as well as in the feces of patients with pernicious anemia. There is, therefore, no reason to believe that a dietary deficiency of this factor is the cause of disease." Other authorities say the same. Many scientists condemn vegetable foods as lacking in vitamin B12, but they never state that there is absolutely *no* vitamin B12 in vegetable foods. Indeed, they wish us to believe that it is totally lacking and this is simply not true. The *Heinz Handbook of Nutrition* (page 111) gives the following inadequate table but even if we ate the small amount of 100 grams of green beans, beets, carrots, and peas, even leaving out the cereal products, we would have half of our so-called minimum daily requirement of vitamin B12, providing our digestion and absorption are normal.

## Vitamin B12 In Foods

Micrograms per 100-gr edible Portion

Green Beans	0-0.2
Beets	0-0.1
Bread, Wholewheat	0.2-0.4
Carrots	0-0.1
Oats	0.3
Peas	0.0-1.0
Soybean Meal	0.2

*The Heinz Handbook of Nutrition* states that, "A dosage corresponding to one microgram of the crystalline vitamin per day is sufficient for maintenance of a patient with pernicious anemia. This indicates the absorption of one microgram per day meets the normal requirement for adults."

The *Nutrition Almanac* states that, "In nature, we find the B-complex vitamins in yeast, green vegetables, etc., *but nowhere do we find a single B vitamin isolated from the rest.* Natural forms of the B vitamins are preferable to the synthetic forms since the natural forms have all of the B factors, even those not yet known, plus valuable enzymes." This is just another indication that people are mistaken when they state that vegetables do not have vitamin B12 in them. Simply because it exists in such miniscule amounts that it may escape detection by present day methods, does not mean it is absent.

Best and Taylor say that all the B vitamins are grouped together because they are found together in Nature. They couldn't be separated one from the other for a long time, so they were thought to be one vitamin. He intimates that where other B vitamins are found there also will be cobalamin. "Twelve substances are grouped together because of their close association in tissues and because for a long time their separation proved most difficult: thiamine, riboflavin, nicotinic acid, pyridoxine, pantothenic acid, biotin, para-aminobenzoic acid, folic acid, folic acid, cyanocobalamin, choline, and inositol. All have been isolated in pure form, and most of them have been synthesized in the laboratory."

Another indication that vitamin B12 is in fruits, nuts, seeds and vegetables containing the other B vitamins is in Rodale's book entitled *The Complete Book of Vitamins* (page 236). "As you know, the B complex of vitamins is called a 'complex' because, instead of being one vitamin, it has turned out to be a large number of related vitamins, which appear generally in the *same* foods." We need such a microscopic amount of vitamin B12, it is not understandable why he urges people to eat so much liver and other foods containing vitamin B12, when excess is not necessary for health, in fact, an excess of anything has only proved to be detrimental to health. I suppose he is assuming everyone eats refined products, drinks coffee, smokes, and takes antibiotics; these practices do produce deficiencies, as some cause the excessive utilization of the B vitamins.

Recently researchers have been coming to the conclusion that Dr. Shelton came to many years ago regarding the "Intrinsic Factor." Dr. Shelton surmised that it was poor digestion that prevented the people from absorbing vitamin B12 and that there was nothing mysterious about it and that the intrinsic factor was simply a normal supply of digestive enzymes. In other words, Castle, who discovered the

*Intrinsic Factor*, which has never been isolated from gastric juice, was wrong in thinking that there was a particular substance in gastric juice necessary for the absorption of vitamin B12.

This "particular substance" is simply good digestion. Vitamin B12 comes combined with protein. In order for the vitamin to be absorbed the protein must be split off so that the vitamin can be combined with the necessary substances, thought also to be protein. Dr. J.G. Heathcote and Dr. F.E. Mooney of St. Helena's Hospital, London, stated that, in spite of an enormous amount of work, there is very little agreement among researchers even on limited properties of the supposed intrinsic factor. They say that "it has never been isolated or identified." This is still true. They "believe, therefore, that intrinsic factor as currently understood, has no real existence per se, and that the fundamental process preceding absorption of vitamin B12 is simply one of normal degradation or digestion of animal protein." Rodale, *The Complete Book of Vitamins*, page 241.

There are many causes of impaired digestion but suffice it to say that *Hygienists* should realize if they abuse their stomachs and intestines by overeating they may eventually suffer malabsorption problems.

It is well known that almonds, asparagus, beans, cashew nuts, figs, lentils, peanuts, pecans, avocado, brussels sprouts, cauliflower, collards, fresh and dried peas of all kinds; plums, raisins, walnuts (black and English), contain vitamin B1. Since all the B vitamins are usually grouped together, in all likelihood there must be some vitamin B12 in these and other vegetable foods.

One of the problems with modern *Hygienists* is that they are afraid to eat nuts. They are so fearful of eating an excess of nuts that they eat far too few. We took Raven Rose Haag off all dairy products at the tender age of fourteen months and fed her nuts. She did not like nut milks and would not drink them so we blended her nuts and let her eat as much of them as she desired. She may have had an excess but her health never showed it. She grew perfectly. Those of you who saw her at the convention can vouch for the fact that her rosy cheeks, happy, smiling disposition and vitality certainly does not indicate anemia. She will be three years old in October.

There is no source that states that vegetables contain absolutely no vitamin B12. The *Cyclopedia of Medicine* says that vegetables contain practically no vitamin B12, in contrast to their high content of folic acid. Simply because animal foods are so very high in vitamin B12 causes all researchers to underestimate the fact that vegetables do contain vitamin B12. Although vegetables do not synthesize vitamin B, the soil bacteria do, and some sources state that the bacteria make the vitamin and actually hand it over to the higher plants. All the plant has to do is absorb it.

Not until we are furnished with a reliable source of information, and not until they have tested all fruits, vegetables and nuts, can we say that *Hygienic-Vegans* are unable to secure a sufficient amount of vitamin B12 from their diets.

According to most nutritionists and health authorities, strict vegetarians must take pills, or eat animal foods, or suffer with a B12 deficiency and die of neurological and blood disorders. This has not been proved by scientists and in another article I will definitely show this. Vegans are not suffering from pernicious anemia and they are healthy, in fact healthier than their meat eating friends.

Some animals secure their cobalamin (vitamin B12) by eating manure which is a very rich source, because it seems to be produced by bacteria in various parts of the guts of animals. Ruminants are furnished B12 or cobalamin by microorganisms which produce it in their digestive tracts. But in poor slighted humankind, the current thought is that the vitamin B12 produced by bacteria in his gut can't be absorbed. This has been shown to be false and there are experiments that lead us to believe that cobalamin manufactured by bacteria in the intestinal tracts of primates can be absorbed.

A few years ago I wrote an article about vitamin B12 and I said that if vitamin B12 is not in fresh fruits, vegetables and nuts, and bacteria do not manufacture it where humans can absorb it, then we do not need it. The diet to which man is constitutionally adapted should furnish all the requisites of good nutrition. If it isn't present in the diet and bacteria do not produce it where it is absorbable by man, then what can we think except that we don't need it or Nature must have made a great big mistake. She neglected to take

care of her most perfect creature.

We know *Nature* did not neglect man. I hold that the vitamin is in our foods. I also have facts which give me reason to believe that bacteria in the stomach, and in the upper and lower small intestine, produce it for us. I also believe that it is absorbed from the small intestine in humans and I have articles which show that, in at least one primate that was studied, this must take place.

You must rest assured that we do not have to resort to pills, algae or animal parts, to secure our Vitamin B12. Nature did not forget humankind. All this scare about vitamin B12 is just a big hoax and it is done purposely by newspaper and nutrition propagandists to keep people from becoming vegetarians, and to sell meat, dairy products, vitamins and sea weeds.

Eat your nuts, fruits, vegetables, and seeds in good combinations for proper digestion and absorption, all in the uncooked state, and don't take antibiotics and you can be sure that you will secure a sufficient amount of all of the B vitamins and in the proper proportion, one to the other, so that the maximum amount can be absorbed and properly utilized. Don't let yourself be pushed about by every fly-by-night "health authority" who knows nothing about *Hygiene*. Learn your principles and stand up for them! They are as true today as yesterday. Truth does not change.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #17: It's A Lie! Vegans Are Not Lacking In Vitamin B12 by V.V. Vetrano, B.S., D.C.

### **Article #17: It's A Lie! Vegans Are Not Lacking In Vitamin B12 by V.V. Vetrano, B.S., D.C.**

There has been so much controversy about Vegans having a vitamin B12 deficiency that I thought I would go to the sources of information myself and determine what was true and what was not true. I secured an article about Vegans at the University of Texas Medical School library, at San Antonio, and when I read "Haematological Studies on Vegans," the article most often quoted by so-called health "authorities" showing that Vegans are deficient in vitamin B12, I was flabbergasted. *It does not say that Vegans are deficient in vitamin B12 at all. The tests did not show that these people were suffering from anemia.* "The blood counts and films were normal in all the Vegans and no subject had a haemoglobin concentration below the lower limit of normality."

### **Vegan Males Actually Had More Haemoglobin Than Conventional Men On An Omnivorous Diet**

"Although within the normal range, male (but not female) Vegans had lower values for *erythrocyte* counts and higher values for mean corpuscular volume and mean corpuscular haemoglobin than their controls." This simply means that the red blood cell count was normal in male and female Vegans, but lower in Vegan males than in the control group. It also means that the haemoglobin in Vegan males was higher than in the meat eating controls, showing that their red blood cells could carry more oxygen than the omnivorous controls. Also their mean corpuscular volume was higher. The quote follows:

"Although the blood films were normal, a number of statistically significant differences were noted between the Vegans and their omnivore controls: in the male but not the female Vegans the mean values for erythrocyte count and packed cell volume were lower ( $R < 0.01$  and  $R < 0.05$ ) and the mean values for mean corpuscular haemoglobin and mean corpuscular volume were higher (both  $P < 0.01$ ) regardless of whether they were taking vitamin B12 supplements or not: the mean values for serum vitamin B12 concentration was lower in the Vegans not taking vitamin B12 supplements ( $P < 0.01$ ) and in those using

foods supplemented with the vitamin ( $P < 0.01$ ) but not in those taking vitamin B12 tablets; the mean value for serum folate was much higher in the Vegans ( $P < 0.01$ ); the mean erythrocyte folate concentration tended to be higher ( $P < 0.05$ ) in the Vegans not taking vitamin B12 supplements."

### **The Blood Count And Films Of The Vegan Subjects Were Essentially Normal**

In their discussion of these facts the scientists state that "the blood counts and films of the Vegan subjects were essentially normal, in agreement with Hardinge and Stare (1954a) West and Ellis (1966) and Ellis and Montegriffo (1970). The findings that male but not female Vegans tended to have lower values for erythrocyte counts and higher values for mean corpuscular volume and mean corpuscular volume and mean corpuscular haemoglobin are novel." The researchers do not know what to think of this. They can't understand why a vegetarian can have more hemoglobin than a flesh eater.

### **Female Vegans Were Not Weak: Their Physical Activity Was Considered Normal**

"Cotes, Dabbs, Hall, McDonald, Miller, Mumford & Saunders (1970) found no difference between the physiological response to exercise of female Caucasian Vegans and omnivores; no similar studies of male Caucasian Vegans appear to have been made and would be of interest."

### **None Of The Vegan Subjects Studied Had Vitamin B12 Deficiency**

Actually the Vegans had normal erythrocyte folate concentration, which indicates no B12 deficiency. "The finding of lower serum vitamin B12 and higher serum folate values in Vegans is in agreement with previous reports (West & Ellis, 1966; Ellis & Montegriffo, 1970). Erythrocyte folate concentrations in Vegans do not appear to have been previously reported. The level of serum folate is often increased in patients with untreated pernicious anemia, while the erythrocyte folate concentration is abnormally low (Chanarin, 1969) apparently because vitamin B12 is necessary for the uptake of folate into the erythrocyte (*Nutrition Reviews*, 1975) *In this study none of the Vegan subjects had an abnormally low erythrocyte folate concentration; this would suggest: first, that none of the subjects was suffering from vitamin B12 deficiency and, second, that the high serum folate concentrations found in many of the Vegan subjects were due to high dietary intakes of folate. This might explain why megaloblastic anemia was not encountered in our Vegan subjects.*"

### **No Vegan Subjects Had A Serum Vitamin B12 Concentration Indicative Of Deficiency (less than 80 ng/l WHO 1968)**

Who says that the Vegans were lacking in vitamin B12? Even those Vegans who were not taking supplements or foods supplemented with vitamin B12 had what is considered normal serum levels of vitamin B12. All their blood cells were normally structured, not overly large or undersized. "*No subject had a haemoglobin value below the lower limit of normality (13.0 ng/l for males, WHO 1968; 11.5 ng/l for females, Chanarin 1969). No subject had a serum vitamin B12 concentration indicative of deficiency (less than 80 ng/l WHO 1968) or a serum folate level less than 2.5 ug/l. There was no evidence of macrocytosis or, microcytosis, no polysegmented neutrophils were seen and all the blood films were normochromic when examined.*"

It is really pathetic and downright dishonest when newspaper reporters take half information and misinformation and spread actual lies to the public. These Vegans proved to be healthy in all ways despite not being strict *Hygienists*. It would be interesting to have a study of Vegan-Hygienists who live on all uncooked foods.

There appears to be some disagreement among the researchers. Rose (1976) claimed that megaloblastic anemia is a predictable consequence of the Vegan dietary habits adopted in Britain. But the findings failed to show it. "Vitamin B12 is a product of microbial synthesis and is not found in plant foods

(Lester Smith, 1965) and therefore should be absent from Vegan diets." If it was absent from Vegan diets, then why did they not develop anemia? Why did Hardinge and Stare (1945a), West & Ellis (1966), and Ellis & Montegriffo (1970) fail to find "any clinical or haematological evidence of vitamin B12 deficiency in their studies of Caucasian Vegans, although the serum concentrations of some of their subjects indicated deficiency." They were not sick. Perhaps absorption was not quite up to par in some of them. However, they were not anemic. Perhaps what is considered normal vitamin B12 serum levels is too high. Vegetarians not smoking and not drinking coffee don't require as much vitamin B12 as a conventional person who continually poisons himself or herself.

## **All The Vegans Were Healthy**

"All the Vegan and omnivore subjects seemed healthy when studied. The Vegan subjects had been on the diet for an average of seven years (range: six months—30 years).

## **Six Healthy Subjects Were Breast-Fed By Vegan Mothers**

The propaganda that every Vegan mother is lacking in vitamin B12 is sheer nonsense. Vegan mothers can nurse their babies as well as any omnivore and probably even better if they ate more raw foods and nuts. "Six subjects had been born of and breast-fed by Vegan mothers and weaned and reared on a Vegan diet. None of the Vegan subjects admitted eating meat, fish, eggs, milk products, or any other foods of animal origin."

Some of the Vegans were taking food supplements containing vitamin B12 and some were taking vitamin B12 tablets but the important fact is that those not doing so came out just as well in the tests as those using supplements, "...ten subjects were taking neither tablets nor foods supplemented with the vitamin. The mean serum vitamin B12 concentration was higher in those Vegans taking vitamin B12 tablets than those using foods supplemented with the vitamin (421+70 ng/l (mean  $\pm$  SE) compared with 253  $\pm$  19; P<0.05). Four of the ten subjects who were not taking vitamin B12 supplements had normal serum levels of the vitamin (greater than 180 ng/l): their vitamin B12 values were 200, 230, 220 and 235 ng/l, and they had been on the diet for 2, 6, 3 and 4 years respectively." If vitamin B12 is not in their diet then they are getting it from somewhere. It is probably in their diet and also being manufactured by their own microbial flora in their intestinal tracts. They are probably absorbing it very well.

## **Conclusion: The Present Study Finds No Lack Of Vitamin B12 In Vegans.**

"Vitamin B12 is the vitamin most likely to be deficient in Vegan and occasionally vegetarian diets. The present study has provided no evidence of pathologically low values of vitamin B12 in the serum of Vegans. In twenty-four of the subjects this could be attributed to their taking vitamin supplements or foods supplemented with the vitamin. There were, however, ten subjects who did not take supplements and it was, therefore, surprising that these subjects did not show evidence of vitamin B12 deficiency. Some Vegans may obtain the vitamin through the accidental ingestion of insects or from microorganisms, that produce the vitamin in their food or as a result of poor personal hygiene. Alternatively, some Vegans may be able to absorb vitamin B12 which has been synthesized by their own, micro flora." This is the usual way B12 is made. Recent evidence strongly points to the fact that primates absorb vitamin B12 manufactured by bacteria in their own intestines.

Researchers denigrate and insult people if people don't respond the way they should to their current theories and hypotheses. To state that Vegans are dirty and that they don't wash their vegetables well, and that their hygiene is poor is mudslinging. Vegans are among the thinking population. They are every bit as clean as omnivorous people, if not cleaner, because they probably realize that cleanliness is a part of a healthful program and many of them are thinking of health as well as of kindness to animals and people. I am sure that Vegans are absorbing some vitamin B12 that is synthesized by their intestinal flora.

## **Diagnosis Of Vitamin B12 Deficiency And Disease Found In Vegans Is Questioned Even By Authorities**

I do not doubt the above subheading one bit. The conventional meat-eating scientists are so anxious to find something wrong with vegetarians that they blind themselves. The study I read intimates that the former diagnoses of blood and neurological disorders among Vegans were not very convincing. "A few cases of vitamin B12 deficiency, sometimes resulting in neurological symptoms, have been reported in Caucasian Vegans apparently due to dietary deficiency (Badenoch, 1952; Wokes et al. 1955; Smith, 1962; Hines, 1966; Verjaal & Timmermans-van den Bos, 1967; Winawer, Strieff & Zamcheck, 1967; Ledbetter & del Pozo, 1969; Misra & Fallofield, 1971. The results provided by Badenoch (1952), Wokes et al. (1955) and Smith (1962) are incomplete and their diagnoses of sub-acute combined degeneration of the spinal cord due to vitamin B12 deficiency are not convincing (Pallis & Lewis, 1974). However, this and other studies (Hardinge & Stare, 1954a; West & Ellis, 1966; Ellis & Montegriffo, 1970; Armstrong, Davies, Nichol, Van Merwyk & Larword, 1954) *failed to find symptoms attributable to a dietary deficiency of vitamin B12. This would suggest that dietary vitamin B12 deficiency is rare among Vegans.*"

So you see, it was all a hoax. The second group of scientists did not confirm the findings of the first group of scientists. Flesh eating people, on a diet of refined carbohydrates suffer with the most cases of pernicious anemia. I am sure that if statistics were made of all vegetarians, one would find more cases are found in flesh eating individuals than in the vegetarians. One would probably also find that the vegetarians were healthier on the whole than flesh eaters.

## **Never Believe The Final Conclusions Of A Flesh Eating Scientist**

Always read the fine print. Never believe the conclusions of flesh eating scientists. This is exactly how and why ordinary news media all tell lies. Reporters take one sentence from a research paper and enlarge and elaborate on this and make a wild tale that would cause you to believe that all vegetarians, and especially Vegans, are deficient in vitamin B12. This simply has not been proved. After saying that the Vegans were normal, the scientists who presented the present study have the gall to say: "However, as there is a *possibility* of developing symptoms of vitamin B12 deficiency, Vegans should supplement their diets with the vitamin."

## **It Was Actually Found That The Vegans Were Healthier Than The Omnivore Controls And Less Prone To Cancer**

The researchers won't actually come out and say it but they state that the Vegans would *probably* be less prone to ischaemic heart disease. The researchers do condescend to say that the Vegan diet will only probably promote normal blood formation, after showing that it definitely DOES in their study. They are so afraid to actually admit anything that it is shameful. They prove that the diet is good but they can't accept it. It is too foreign to their flesh eating minds, or they don't want their backers to think they are swayed by their findings less the subsidies be withdrawn and they lose their jobs. Consequently they keep playing down their actual findings. The last paragraph of their conclusions follows.

"The health of Caucasian Vegans appears to differ little from that of omnivores (Hardinge & Stare, 1954a; Ellis & Montegriffo, 1970; Ellis, West & Saunders, 1976; Sanders, 1977). Pregnancy in Caucasian Vegans and the health of children reared on Vegan diets appear to be essentially normal (Thomas, Ellis & Diggory, 1977; Mumford & Ellis, unpublished observations; Sanders, 1977). Caucasian Vegans tend to have lower concentrations of serum cholesterol and triglycerides and less body fat than omnivores (Hardinge & Stare, 1954b; Sanders, 1977) which suggest that they may be less prone to ischaemic heart disease than omnivores, and according to Aries, Crowther, Drasar, Hill & Ellis, (1971), Caucasian Vegans are probably less susceptible to cancer of the colon than omnivores. The Vegan diet appears to be adequate provided it comprises a mixture of unrefined cereals, pulses, nuts,

fruits and vegetables and is supplemented with vitamin B12 and D; such a diet will generally promote normal blood formation."

I can't believe it. After proving that the diets of Vegans not taking vitamin B12 supplements were normal, they still advise that Vegans take supplements. I guess they can't believe their own facts and figures. What a pity! They might learn something if they could open their minds.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Article #18: A Normal Source of Vitamin B12 by V.V. Vetrano, B.S., D.C.

### **Article #18: A Normal Source of Vitamin B12 by V.V. Vetrano, B.S., D.C.**

It has long been difficult to produce a vitamin B12 deficiency in animals (Stokstad 1968). Yet, this is exactly what scientists tried to do to baboons in a study done by Uphill, Jacob and Lall, at the Wellcome Trust Research Laboratories, P.O. Box 43640, Nairobi, Kenya.

In the manuscript written by Uphill, Jacob and Lall there are several contradictions. At one time it is stated that, "The production of vitamin B12 deficiency in animals is known to be difficult (Stokstad 1968) and in this laboratory the feeding of a vitamin B12-deficient diet to baboons over a two-year period resulted in the development of a *subclinical* deficiency of the vitamin (Siddons 1974)." Then they tell us how they produced the "subclinical" deficiency. "It was shown however, that the vitamin B12 deficiency was more severe in baboons fed a diet containing ampicillin, suggesting that the intestinal flora may play a part in the vitamin B12 nutrition of the baboon." They never really found a deficiency in all the animals. Some animals actually had a high serum vitamin B12 level. Some writers taking the foregoing statement out of context will convince people that a vitamin B12 deficiency can indeed be produced in baboons, when it can't. The so-called deficiency was subclinical and never caused disease in the animals. It was merely a low serum vitamin B12 level. Even if they had produced a real deficiency it would not have meant anything because the experimental diet was so inadequate in every known nutrient, containing only synthetic vitamins and minerals, that for all purposes the animals were just subsisting, and probably living largely on stored nutrients.

They continue: "In addition, a group of young baboons fed a vitamin B12-deficient diet were found to have high serum and liver vitamin B12 levels after 18 months, in comparison with older animals fed the same diet. The intestinal flora of young animals has been shown for many species to be different from that of adult animals (Smith & Crab 1961). This study was undertaken to determine whether there were any detectable differences in vitamin B12 production by the intestinal flora of the baboons which could explain these findings."

They also state that, "Samples of gastric and small intestinal contents, obtained at laparotomy from two young vitamin B12-deprived baboons, contained varying quantities of vitamin B12. Many of the organisms isolated from these aspirates produced vitamin B12 in vitro. The highest levels of vitamin B12 were produced by anaerobic organisms."

The experimental animals were fed a diet completely free of all nutrients except synthetic ones. It is a wonder that any of the baboons remained healthy. The basal synthetic diet consisted of vitamin free casein, sucrose, corn oil and a mineral salts mixture, together with a vitamin mixture. Some were given a diet deficient in vitamin B12 and some were supplemented with vitamin B12. If you are interested in the exact diets of all the animals, I suggest that you secure a reprint of the article. The feeding of the animals and separation into control groups were extremely varied and would take up too much valuable space to reprint it all here. Some had the basal diet supplemented with vitamin B12; others had a vitamin B12 deficient basal diet; and some had the basal diet but low in fat and containing sodium propionate; and some had ampicillin added to the vitamin B12 deficient diet. Both sodium propionate (a preservative

used in baking goods) and ampicillin probably had detrimental effects on the microbial flora of the baboons' intestinal tracts.

"Many intestinal microorganisms are known to produce vitamin B12, often in an amount in excess of the host's requirements (Mickelsen 1956). However, the site of vitamin B12 production in the intestine is important when considering the potential availability of the vitamin to the host, since vitamin B12 absorption is reported to occur in the upper part of the alimentary tract (Matthews 1967). Ruminants, although feeding on a diet of plant material totally devoid of vitamin B12, have been shown to have high levels of the vitamin in their rumen contents (Hungate 1966). Due to the anterior position of the rumen, its content must pass through the remainder of the alimentary tract, so allowing maximal opportunity for vitamin absorption. In other mammalian species and in birds the densest intestinal microbial populations normally occur in the caecum and colon. Vitamin B12 produced by microbial action in these areas is considered to be excreted, unutilized, in the faeces. Coprophagous species are an exception in that they obtain a considerable part of their vitamin requirements by ingestion of their faeces."

In the article quoted above, the authors skirt all around the truth, never quite willing to admit that baboons also have bacteria in the upper intestines that form vitamin B12. In the aforementioned experiment it was clearly demonstrated that baboons have the microbial flora in their stomachs and small intestines that produce vitamin B12. Even though they demonstrated that the baboons fed on a diet deficient in vitamin B12 nevertheless have vitamin B12 in their serum, they seem reluctant to admit that this can happen. They succeed in producing a near deficiency of B12 by feeding some of the animals 50 mg/kg of ampicillin a day (an antibiotic). Naturally this will destroy some of the bacteria and prevent vitamin B12 from being formed. Since all the B vitamins are interrelated, and since some are necessary for the absorption of others it is understandable how some older animals may be deficient, being on such a synthetic diet.

It was clearly shown that microorganisms capable of producing vitamin B12 were isolated from the gastrointestinal tracts of the animals who were deprived of vitamin B12. "A greater variety of organisms was isolated from baboon A. However, baboon B had eaten very little of the food offered to it 6 h prior to laparotomy."

An interesting point observed was that yeasts were not the organisms that formed the most vitamin B12 in the baboons. "The levels of vitamin B12 produced by organisms isolated from baboon faeces are compared. A total of 126 strains of yeasts and aerobic organisms were isolated of which only 9.5% produced up to 1.0 ng/ml, vitamin B12. In contrast, of 123 strains of anaerobic organisms isolated, 48% of cultures contained > 1.0 ng/ml vitamin B12, and 23.6% of cultures, mainly Gram negative rods, contained >10 ng/ml. There were no noticeable differences in the types of faecal organisms isolated from controls or baboons fed any of the vitamin B12 deficient diets, with the exception of the group fed ampicillin. The faeces of these animals contained very few aerobic or anaerobic Gram positive organisms, the flora consisting mainly of aerobic and anaerobic Gram negative rods and yeasts. The patterns of vitamin B12 production by the faecal organisms were similar both within the vitamin B12-deficient groups, and between the vitamin-deficient and control groups."

### **Vitamin-Deprived Baboons Had More Bacteria Working For Them**

The group of baboons fed a vitamin B12 deficient diet showed that more bacteria capable of forming vitamin B12 were in their gastric juice samples. "Table 4 compares the vitamin B12 produced in cultures of organisms isolated from gastric juice samples aspirated 6 h after feeding, from vitamin B12-deprived and control baboons. The number of isolates obtained from the gastric juice samples from the control group was low in comparison with the vitamin deprived group. There were also fewer isolates producing the higher levels of vitamin B12 obtained from the control baboon gastric samples. No organisms producing > 10 ng/ml vitamin B12 were isolated from the gastric juice samples." This definitely proves that bacteria capable of producing at least 10 ng/ml of vitamin B12 are in the baboon's stomach and, therefore, there is, definitely a chance for absorption of vitamin B12 as the stomach contents move to the

small intestine.

## **Humans Have Anaerobic Organisms Producing Vitamins In The Colon**

It is very possible that the bacterial flora of humans also produces vitamins for us in the stomach and small intestine where they can be absorbed, and not only in the colon. For several years now, I have held to this view, because it is well known that the ileum, that part of the small intestine nearest the colon, has a purpose. It begins to take on the anatomy of the colon. Less digestion and absorption of other nutrients occurs here. Recently it has been shown by experiments that this area is the greatest area of absorption of vitamin B12. Bacteria that produce the most vitamin B12 are those which grow in the absence of air, anaerobes, and these are present in the stomach and small intestine.

It is well known that anaerobic bacteria exists in the human digestive tract just as they exist in the baboon digestive tract. Vegans not taking supplements, who were part of an experiment, had no deficiency of vitamin B12. If it was not in their food as some scientists claim, then it had to be formed by the host's microbial flora. "The highest levels of vitamin B12 were produced by the anaerobic isolates, in particular by *Clostridium perfringens* and some of the anaerobic Gram negative rods."

## **There Is No Way Getting Around It—Vitamin B12 Is Produced In The Stomach And Upper Intestine Of Primates**

Baboons have bacteria in their stomachs and intestines which produce vitamin B12. They are primates. So is humankind a primate.

This implies that people also have the bacterial flora to produce vitamin B12 and that this can be absorbed in the ileum.

There are anaerobic bacteria in human gingiva. Were they to make more studies on these bacteria, I'm sure they would find that they also produce vitamin B12. It is essential that we understand that the vitamin levels that the bacteria produced differed when the food they were fed was different. If these bacteria are fed properly in our own intestines I am sure that the levels of B12 would increase. If we humans live on the diet to which we are constitutionally adapted, not only will we be properly nourished, so will our bacterial flora, and they in turn will produce for us the necessary elements for a proper nutrition in levels far more than we actually need.

## **Vitamin B12 Is Reused Like Iron**

Vitamin B12 circulates. It is excreted with bile and reabsorbed like bile from the intestines. It can be used over and over again. It is stored in the liver. Our body is intelligent. It knows what it is doing.

The ileum has its purpose, even if we mortals can't figure it out. Probably other even unknown nutrients are also formed for us in the intestines by bacteria. If we would quit feeding ourselves poisons, and eat a diet for which we are anatomically, physiologically and biochemically designed we would see a health unparalleled in modern times. Our health could equal that or surpass that of the animals in the wild if we would cultivate it half as much as we cultivate enervating habits.

"It has been shown that vitamin B12 was present in the stomach and upper intestine of two of the young vitamin B12 deprived baboons. In addition some of the microorganisms isolated from the gastrointestinal contents of these baboons were capable of producing *in vitro* large quantities of vitamin B12. However, gastric juice samples from all the vitamin deprived and control baboons contained organisms capable of producing vitamin B12 *in vitro*. No differences were detected due to different diets or age of animal, with the exception of the baboons receiving ampicillin. Therefore, the unusually high serum and liver vitamin B12 levels found in the young animals, but not in older baboons, remains unexplainable."

I guess the researchers must be very careful about not assuming anything, this is why they are very careful in not stating that vitamin B12 is actually produced *in vivo* in the animals deprived of vitamin B12. But, organisms don't cease functioning when they find themselves in the intestinal tracts of animals. To cease functioning would be to die and they were found alive very capable of producing vitamin B12.

### **The Study Provides Presumptive Evidence That The Vitamin B12 Found In The Baboon Stomach And Upper Intestine Could Have Been Produced By Microbial Action**

After beating about the bushes for about a half hour, they finally come up with the above presumption.

"Vitamin B12 found in the gastrointestinal contents of vitamin B12 deprived baboons could be derived from ingested food, desquamated epithelial cells, digestive secretions or from the bodies and/or the secretions of the gastrointestinal microflora. Siddons (1974) reported that the vitamin-free casein used in these studies contained 0.004 ug/gr *L. leichmanni* growth-promoting ability, which, if it was due to vitamin B12 could result in each baboon receiving 0.01 ug vitamin B12 a day. The three baboons fed the soya protein diet did not receive even this minimal supplementation however, but the mean 18 H and 6 h fasting gastric samples also contained high levels of the vitamin. The vitamin B12 content of desquamated epithelial cells or digestive secretions is unlikely to account for all of the vitamin B12 found in the stomach contents of baboons deprived of the vitamin. These animals were showing evidence of vitamin B12 deprivation in their low serum and liver levels (Siddons 1974) but the mean vitamin B12 levels in their stomach contents 18 H after feeding were not significantly lower than those of control baboons. It would be impossible to state conclusively that the intestinal flora were largely responsible for the vitamin B12 found in the baboons stomach and intestine, since production of the vitamin by an organism *in vitro* does not necessarily mean that comparable levels would be produced *in vivo*. However, this study does provide presumptive evidence that the vitamin B12 found in the baboon stomach and upper intestine could have been produced by microbial action."

Vegans also had lower serum levels of vitamin B12 but their high folate count made up for this and their blood cells were normal. Normal values for serum vitamin B12 for vegetarians and frugivores have not yet been established. If no disease develops and the animals and people remain healthy then evidently their supply of vitamin B12 is adequate.

They finally get around to making a few conclusions. "Assuming that the vitamin B12 produced by these organisms *in vitro* was also being produced *in vivo* in the baboon stomach and upper intestine, it is possible that the vitamin was being absorbed and utilized to meet part of the animal's nutritional requirements. Vitamin B12 produced by the Gram positive flora was unavailable to the baboons fed ampicillin and their vitamin B12 deficiency was increased."

### **They Can't Really Produce A Deficiency Of B12**

That they can't really produce a vitamin B12 deficiency in baboons is clearly intimated in the following sentence. "This study suggests that the chances of producing a vitamin B12 deficiency in the baboon might be improved by a change in its feeding habits." By operating on animals and cutting out normal body parts they can achieve their goal. "Smith (1956), showed that in fowls with ablated crops, the bacterial content of the alimentary tract was lower than in ordinary fowls." Surgeons do the same in people. By cutting out over half of some of their patient's stomachs, it's very easy to produce a vitamin B-12 deficiency. There's very little glandular tissue left to secrete digestive juices. To produce a deficiency of vitamin B-12 in baboons, the following is proposed: "Closure of the baboon facial pouches might also lead to a reduced intestinal bacterial population. In addition, the baboons used in this study were fed their daily ration in two meals with an interval of 5 hours between. The results show that vitamin B-12-producing organisms would therefore be present in the upper intestine for at least 12 out of

every 24th. The feeding of only one large meal/day and a change of diet to a type less likely to cause an increase in the putrefactive and potentially vitamin B-12 producing flora could speed the development of vitamin B-12 deficiency in the baboon. Alternatively the gram positive vitamin B-12 producing flora can be eliminated by the daily feeding of small quantities of ampicillin."

There is just no way to completely rid the digestive tract of animals and people of all its bacterial flora except by drugging the animal or person so much that you kill it, him or her. There were a total of 126 strains of yeasts and aerobic organisms that produced even more vitamin B-12. These were not only found in the colon. These were found in the stomach and small intestine of all the animals, those deprived of vitamin B-12 as well as the controls. Organisms producing vitamin B-12 found in the gastrointestinal aspirates of two young vitamin B-12 deprived baboons were yeasts, aerobic gram positive cocci, anaerobic gram negative cocci, micro-aerophilic gram positive rods, clostridium perfringens, other anaerobic gram positive rods (unidentified), aerobic gram negative rods, and anaerobic gram negative rods.

I hold the view that if these organisms produce in vitro vitamin B-12, they will do so even more readily in vivo because that is where they live and grow. It is their natural habitat and it is one of their metabolic functions to produce vitamin B-12.

Humans being primates, also have these same bacteria. They do the same things for us as for the baboons. Are we going to let ourselves be hoodwinked into eating practices that are not ideal just because of unproven propaganda? I venture to say that if a percentage of those with pernicious anemia were studied, that there would be more cases found among omnivorous people than vegetarians and on the whole the vegetarians would be the healthiest specimens.

## **Article #19: Well! You Wanted to Know! by V.V. Vetrano, B.S., D.C**

### **What is vitamin B-12?**

Vitamin B-12 is known as the anti-pernicious anemia factor. It is also called the *extrinsic factor* of Castle. It was first isolated in 1948 from liver as a red crystalline compound which contains cobalt and phosphorus. It is a water soluble vitamin and functions as a coenzyme in metabolism.

It is called cobalamin because it contains cobalt. The central structure, which contains cobalt, is referred to as a "corrin" ring system. One type of cobalamin contains cyanide, but in the latest edition of *The Review of Physiological Chemistry*, (p. 180) by Harper, Rodwell, Mayes and Lange, they say that the "cyanide group as a component of vitamin B-12 is an artifact introduced in the procedure used to isolate the crystalline compound from natural sources. It (cyanide) does not occur in the vitamin molecule as it exists in natural materials."

Cyanide is very toxic and the addition of cyanide to a vitamin does not seem to me to be desirable. It is known that this particular form of the vitamin is eliminated more rapidly than other forms and is not as effective as the other cobalamins, such as hydroxocobalamin. Some scientists think cyanocobalamin should be withdrawn from the market because it is not as effective as other cobalamins. ("Why Has Cobalamin Not Been Withdrawn," Freeman, A. G., *et al*, Lancet 1 (8067) p. 777-8, Apr. 1978). This simply stresses the view that Dr. Shelton and I have held for many years. We have always said that the mere extraction of vitamins from natural foods changes their character and renders them unfit for use, in

as much as they are no longer combined with natural substances as they were in the natural food and are therefore digested and metabolized differently. The extraction of cobalamin from natural sources actually adds a toxic substance, cyanide, to the structure.

By reacting cyanocobalamin with other substances, it can be made into other derivatives of cobalamin. "Substitution of the cyanide group with a hydroxy group forms 'hydroxocobalamin'; with a nitro group, 'nitrocobalamin'; and with a methyl group, 'methylcobalamin'. The biologic action of these derivatives appears to be similar to that of cobalamin, although hydroxocobalamin (B-12A) is more active in enzyme systems requiring B-12 in experimental studies in vitro. Furthermore, although hydroxocobalamin given orally in large doses is absorbed as well as cyanocobalamin in similar doses, hydroxocobalamin is retained longer in the body; this suggests that hydroxocobalamin may be more useful for therapeutic administration of vitamin B-12 by mouth." The fact that it is eliminated more slowly than cyanocobalamin from the body could mean two things; either that it is hard to eliminate or that cyanocobalamin is more toxic. Synthetic substances do not function in metabolism exactly like the natural substance. Synthetic vitamins may be used as substitutions and fool people temporarily by masking symptoms, but they never metabolize or function exactly like the natural substance and *taking the so-called "natural" vitamins never produces health.*

The B-12 coenzymes, called cobamides, have been isolated not only from "several bacterial cultures but also from the liver of various animals (mainly dimethylbenzimidazole cobamide). The best source is a culture of *Propionibacterium shermanii* (ATCC 9614). The coenzymes are inactivated and converted to the vitamin form by visible light or by cyanide ion, the adenine nucleoside being removed or replaced by the cyano group. The methods originally used to extract the vitamin included heating in weak acid, addition of cyanide ion, and exposure to light. As a result it is likely that the coenzymes were converted to the vitamin and thus overlooked." (page 181, *Review of Physiological Chemistry*.) This brings to my minds a question. Perhaps they are not finding vitamin B12 in fruits and *vegetables* because it is in the coenzyme form or in another form or perhaps they are destroying it by their methods of finding it. The following quote brings out the fact that all the B vitamins are found together in nature.

The Nutrition Almanac, on page 18, warns that, "The most important thing to remember is that all the B vitamins should be taken together. They are so interrelated in function that large doses of any of them may be therapeutically valueless or may cause a deficiency of others. For example, if extra B6 is taken in 50-milligram potencies, it is important that a complete B complex accompany it. In nature, we find the B-complex vitamins in yeast, green vegetables, etc., but nowhere do we find a single B vitamin isolated from the rest. Natural forms of the B vitamins are preferable to the synthetic forms since the natural forms have all of the B factors, even those not yet known, plus valuable enzymes. Most preparations of single B vitamins are synthetic or, at least, no longer in their natural form. These synthetic B vitamins are used primarily to overcome severe deficiencies or serious physical conditions in which rapid results are needed. When taking supplements, it is very important to remember that the B vitamins exert many different effects upon each other; therefore, *excesses and insufficiencies may be harmful.*"

We heartily agree with *The Nutrition Almanac*. All our nutrients should be secured through natural sources as they all function together and have a relation one to the other, and only by eating natural foods can we get our nutrients in the proper proportions one to the other.

## **How Stable is Vitamin B12?**

Vitamin B12 can be heated at 100 degrees centigrade for long periods under certain conditions. If vitamin B12 is placed in an acid solution in a pH ranging from 4 to 7, that is, in a solution acid up to neutral, it can be autoclaved (steam heat under pressure) with very little destruction of the vitamin. "However, destruction is rapid when the vitamin is heated at pH 9.0 or above." A pH of 9 is very alkaline. Since vegetables are alkaline, this may mean that what little vitamin B12 is contained in vegetables is rapidly destroyed while cooking. This may be why researchers are unable to find this

elusive vitamin in vegetables because they destroy it with heat in trying to extract it.

## **What does vitamin B12 do in the body?**

Vitamin B12 acts as a coenzyme in metabolism. Only three cobalamins have been isolated from mammalian tissues; and of these only two forms of vitamin B12 are known to act as specific coenzymes in mammalian systems. "The two reactions in mammalian systems that are shown to be vitamin B12 dependent are (1) the conversion of methyl-malonyl-Co A to succinyl-Co A; and (2) the methylation of homocysteine to methionine, which also involves folate coenzymes." A disease involving these conversions in metabolism is becoming more prevalent in modern times.

We must remember that vitamin B12 is an essential nutrient for all the cells of the body. It is necessary for the growth of all cells. Vitamin B12 with folic acid derivatives, are also necessary for DNA synthesis, and there are few who have not read of the importance of DNA to the body. When there is a complete lack of vitamin B12, cells can no longer divide, because their nucleus cannot mature. Without vitamin B12 the red blood cells cannot proliferate normally. They are malformed and they die more rapidly than normal cells.

Vitamin B12 is necessary for catalyzing the conversion of methylmalonyl-Co A to succinyl-Co A. Without these chemical transformations many serious symptoms develop.

A deficiency of vitamin B12 in humans causes the development of macrocytic anemia, and/or lesions of the nervous system. Sometimes both occur together. Sometimes the neurologic symptoms supervene without the development of anemia. Structural changes of the red blood cells are very reliable indicators of vitamin B12 deficiency. In this case blood tests may be valuable to determine whether or not you are properly absorbing vitamin B12. "In general, it may be concluded that when the intake of vitamin B12 is low, the demand for this vitamin in hemopoiesis exceeds that for any other clinically recognizable physiologic function. Macrocytosis is, therefore, a sensitive indicator of vitamin B12 deficiency." (page 183, *Review of Physiologic Chemistry*)

## **How do we absorb vitamin B12?**

It has been well established that vitamin B12 is absorbed from the ileum. But its absorption is dependent on a factor called the Intrinsic Factor (IF), first named by Castle. It is present in normal gastric juice. It is secreted by the parietal cells of the gastric glands and is found in the cardia and fundus of the stomach but not in the pylorus: that is, it is found in the upper part of the stomach.

The free vitamin (cobalamin) becomes bound to the intrinsic factor, which is thought to be a glycoprotein. The combination of vitamin B12 with the intrinsic factor results in the formation of a complex substance that resists intestinal digestion.

In foods, vitamin B12 comes combined with proteins, or the protein break-down byproducts, such as peptides. These must be split off by the processes of digestion before absorption can take place. The members of the vitamin B12 group are very large molecules and this is considered the reason it is necessary for them to be combined with intrinsic factor for absorption. The body must actively absorb the vitamin and the cobamides with the consequent expense of energy. They cannot be absorbed by mere diffusion across the intestinal mucous membrane, unless administered in huge doses.

"They are not lipid-soluble and, according to Wilson (1964), the molecules are too large to enter the hypothetical water-filled pores in the lipid membranes of the absorptive cells, so that any absorption by simple diffusion would appear to be precluded."

Experiments conclude that, under physiological conditions, humans can absorb only about 2 ug/day of vitamin B12. Only after the vitamin is combined with intrinsic factor, can it cross the intestinal barrier. If high doses of the pure vitamin are given, however, some can diffuse through the intestinal mucous membrane because of discontinuities. A discontinuity is a sign of a damaged mucous membrane. In

health all the membranes of the intestinal tract will be intact.

The intrinsic factor is a glycoprotein secreted by the parietal cells of the gastric mucosa and is necessary for the absorption of vitamin B12. The first stage of absorption is good digestion. The vitamin must be separated from the materials to which it is bound before it can be combined with the intrinsic factor. In food, B12 compounds are largely protein or peptide-bound and these must be separated from the vitamin by digestive juices before B12 can be combined with the intrinsic factor. Only after separation from the protein, to which it is bound, can the B12 compounds combine with the intrinsic factor. The third stage of absorption is to transport the vitamin B12 into the cells of gastrointestinal mucous membrane.

After vitamin B12 has combined with intrinsic factor it is in a complex form that fortunately resists further intestinal digestion. For normal absorption the pH must be neutral and calcium ions must be present. The vitamin has two receptor sites for absorption and one of them combines with intrinsic factor and the other with the ileal intestinal microvilli. The microvilli readily become saturated and this limits the absorption of vitamin B12 to about 1.5 ug after any one dose of the vitamin. The current thought is that the intrinsic factor is released by a "releasing enzyme" within the intestine, so that the vitamin can pass into the mucosal cell.

Absorption is limited and the maximal absorptive capacity in humans under normal conditions, is about 2.ug/day. Most sources state that humans require only 1 ug/day.

The vitamin, when given in large concentrations is thought to get into the body by passive absorption, but researchers attribute this to discontinuities of the lining of the intestines. About one percent of very large doses of vitamin B12, such as 3000 ug is absorbed passively. The intrinsic factor appears to be necessary for absorption of very small amounts, such as are found in food.

### **Where is vitamin B12 absorbed; Can it be absorbed from the stomach or colon?**

Vitamin B12 is absorbed mainly through the ileum, although there is only evidence that some absorption might also occur in the upper small intestine. Even though research physiologists transpose ileal tissue to other areas of the intestine, it still maintains its superior capacity to absorb vitamin B12. This supports my view held all along before reading this material; i.e. that the ileum had a function and since the colon couldn't absorb vitamin B12, it was probably done in the ileum. It has long been known that bacteria produce vitamin B12 in the colon. If bacteria can do this in the colon why should they not also do so in the ileum, where the absorptive mechanisms are still in operation?

### **Why are some people deficient in vitamin B12?**

There are many reasons why vitamin B12 may be lacking. Most of them center around failure of absorption and not because the vitamins are lacking in the diet. Articles dealing with the pathology of absorption of vitamin B12 classify defects of vitamin B12 absorption into two main groups: (1) "those due to defective gastric secretion (i.e. lack of IF) and (2) those due to defective intestinal absorption."

Naturally if most of the stomach has been excised by surgery there will be little intrinsic factor secreted and consequently little vitamin B12 absorption. "After partial gastrectomy, some IF-secreting mucosa usually remains, and severe impairment of vitamin B12 absorption does not usually occur unless the mucosa of the gastric remnant undergoes atrophy."

Gastric atrophy accounts for malabsorption of many vitamins. Atrophy occurs after many years of irritation to the stomach mucosa by wrong ways of living and especially from wrong ways of eating. The stomach is the most abused organ of the entire body. When each year we pour in chocolate, coffee, tea, alcohol, hot peppers, chemicals, mustard, salt, aspirin, garlic, onions, drugs and other irritants by the tons how can we expect our digestive tracts to remain normal? When we eat all sorts of poor food combinations, so that instead of digestion we get indigestion, how can we expect any nutrients to be left for us? Bacteria use them. The stomach and intestines naturally become irritated and inflamed from all

the decomposition products of bacterial decay.

Put some salt or any one of the above condiments into an open wound and you will readily understand the word irritant. Then when on top of all the above irritants we combine our foods so poorly that instead of digestion we get indigestion and its concomitant poisonous and irritating end products, we have double trouble. Gastric irritation goes from irritation, to greater irritation and finally inflammation, (gastritis or duodenitis, or gastroenteritis, or ileitis, or colitis or all at once.) When these conditions are severe, atrophy is only one consequence. Cancer is another. Ulcers are still another. After many long years of irritation and chronic inflammation, normal functioning cells of the digestive glands die, then digestion is naturally impaired. Not only will the stomach not secrete the intrinsic factor, if it indeed exists, but it will not digest the protein off the vitamin B12 to permit it to be combined with IF for absorption.

Juvenile pernicious anemia is a rare condition. The secretion of intrinsic factor is congenitally absent, but the other secretory functions of the stomach are usually normal. This is just another example of the fact that as a race, we are deteriorating. Recently I've read articles intimating that formerly humans were able to manufacture their own vitamin C. If this is true, then you can see how far the deterioration has gone. A missing enzyme here and there can make a world of difference when it comes to health and life. However, most of the pernicious anemia of childhood is acquired. In these cases it is noted that there is gastric mucosal damage. This again points to the fact that enervation, by wrong living habits, and especially poor care and feeding of children, causes toxemia with the development of diseases that impair the function of the gastrointestinal tract.

There are many reasons why vitamin B12 is not absorbed from the intestines; there are as many reasons as there are enzymes and catalytic reactions. Such diseases as idiopathic steatorrhea, coeliac disease, tropical sprue, and lesions of the small-intestinal wall, such as regional enteritis and intestinal tuberculosis, and intestinal resections—particularly when the ileum is involved, are reason enough for mal-absorption of all nutrients, not just vitamin B12. Other anatomical abnormalities such as small-intestinal diverticula, enteroanastomoses and blind loops of small intestine (blind-loop syndrome) also cause failure of absorption of vitamin B12. Experimental evidence leads researchers to believe that in some cases, especially when surgical blind loops are left in the abdomen and in cases of diverticulosis, where there are stagnating feces, that more bacteria thrive and these use up the vitamin B12 of the host. They also produce toxic factors, which interfere with the absorption of vitamin B12. Bacteria also deconjugate bile salts and impair mucosal function through the toxic effects of free bile acids. Recently cases have been reported of transport defects of vitamin B12 in children and young people. It is familial and associated with proteinuria. "It is quite distinct from juvenile pernicious anemia." People who are infested with fish tapeworm also develop anemia. One reason is that the worm takes up vitamin B12 itself and produces a factor which splits vitamin B12 from intrinsic factor and then finally gastric atrophy develops from the lack of vitamin B12 itself.

Vitamin B12 and folic acid are very important to rapidly dividing cells such as those of the bone marrow and even those cells lining the gastrointestinal tract. They need vitamin B12 for multiplying rapidly, as they are supposed to. Vitamin B12 is also necessary for the absorption of other nutrients from the intestines. A lack of B12 depresses the function of the gastric mucosa. Some cases are attributed "to the production of a *defective intrinsic factor* or *intrinsic factor: B12 complex* as well as to a defective ileal receptor for *intrinsic factor: B12 complex*."

In short, most cases of pernicious anemia or a low level of vitamin B12 arise out of impaired function somewhere along the gastrointestinal tract and not because there is a lack of vitamin B12 in the diet, even in Vegans:

This brings us back to basic *Hygiene*. Remove the causes of disease and the body will heal itself. In these cases of impaired function, fasting, rest, exercise, and sunshine will restore the body's ability to absorb vitamin B12 in all except those who have had their stomachs and intestines surgically excised or impaired by surgical blind loops, and those who were born not secreting the intrinsic factor or with a

defect in metabolism of B12, such as those born with Methylmalonic Aciduria. Even in those cases where gastric or intestinal atrophy plays a part, the improved digestive capacity after fasting, with proper combinations of food, so that there won't be so much decomposition of foods in the intestinal tract will improve absorption. Better food combinations means fewer of the types of bacteria that use vitamin B12 can exist so that the bacteria that do produce vitamin B12 can do their job properly. Less decomposition in the intestinal tract will promote the proper bacterial flora that make vitamin B12 instead of using it.

There are so many intricacies of digestion and absorption that are still unknown, that can go wrong when we are in ill health, that the only way to insure proper digestion and absorption is to maintain good health. No matter which way you look at it, it comes back to the same basic principles of right living. If you live *Hygienically*, eat uncooked natural foods—fruits, vegetables, nuts, and seeds—and secure all the other requisites of physiology then your body will function normally for you and it will absorb all the vitamin B12 necessary for health. *Hygiene* does not need to be changed. We've got to realize where the real fault lies and eliminate it. Dosing our people with vitamin B12 instead of removing causes is the same as giving drugs. If we start this, it won't be long before we are among the poisoning profession. All it takes is that first blind compromise.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Case History: How We Suddenly Became Vegetarians by Arthur S. Harris, Jr.

### **Case History: How We Suddenly Became Vegetarians by Arthur S. Harris, Jr.**

(A didactic word on vegetarianism)

For forty-nine years I ate meat the way most Americans do—without questioning the practice from any point of view—health, aesthetics, ecology. You might say I had been indoctrinated into meat-eating by society. But four years ago at the age of fifty I gave up meat completely; my wife followed the next month and one of our sons a year later.

A six month's trip to Mexico changed everything. On a tight budget, we drove down to Oaxaca and then to Puerto Angel living as inexpensively as we could. In Puerto Angel, we rented an adobe house for \$16 a month and lived surrounded by Mexicans who slaughtered animals in the early dawn. Agonizing cries of animals in their last moments of life would pierce the predawn darkness. Then, not thirty yards from our hammocks, meat would be cut up. Suddenly we were confronted with the fact that meat comes from a corpse. In our naivete we had allowed ourselves to think meat came attractively wrapped from the A&P meat counter. Going to the nearby dusty town of Pochutla didn't help. Here chunks of meat hung on hooks in open air stores with flies buzzing around.

We had been jolted out of our innocence. We stopped eating meat and made do with fantastically inexpensive vegetables and fruits, supplemented by dairy products.

Back in more civilized Oaxaca, we ate one or two American-style hamburgers but found them hard to get down. Visions of an animal being killed with a machete to the throat kept interfering.

Now, into Oaxaca flow a steady stream of young, knap-sacked Americans who sip capuccino on the zocolo and talk of cosmic consciousness, Mexican police, Vedic studies, and the Allman brothers. We picked up with a young couple into nutrition and spent days learning from them. They were, of course, vegetarians, but they expanded our awareness beyond health to point out that meat-eating consumed vast amounts of protein in a world with a protein shortage. They made us realize that an animal is a protein factory in reverse, consuming tons of protein-rich grains and soybeans to produce mere pounds of chemically-injected animal protein. By the time we left Mexico to return to New York, we were no longer meat eaters. Within a year we gave up fish and chicken, then Phyllis gave up eggs. Technically, I suppose we can be catalogued as lacto-vegetarians.

We are astonished when people ask us if we don't feel weaker. They ask how we possibly get enough protein without good, red meat. When we tell our questioners that we feel better, cleaner, healthier and stronger than ever, we get those glazed-eye looks which say, "Veggies are brainwashed nuts!" But we know better and we know who the brainwashed really are—American meat-eaters who've never once questioned the practice of eating animal flesh as the mainstay of their diet.

[Home](#) > [Lesson 32 - Why We Should Not Eat Meat](#) > Dark Humor: Rigor Mortis on the Dinner Plate by Coleman McCarthy Washington Post

## **Dark Humor: Rigor Mortis on the Dinner Plate by Coleman McCarthy Washington Post**

WASHINGTON—Thanksgiving, America's day of tribute to carnivorism, isn't likely to have the same turkey-chomping merriment of years past. Marian Burros, the journalist-cook-dashing spirit who favors simplicity in her kitchen and factualness in her prose, has seen to that. She talked turkey the other day in the New York Times.

Birds served by Grandma, said Burros, are all but a vanished species. Most of today's turkeys "have been frozen and filled with ingredients no self-respecting turkey should contain...Much of the flavor has been bred out of turkeys, so whether they are fresh makes little difference."

For the fresh-is-better dreamers, Burros, whose current best-selling cookbook is *Keep It Simple*, salted her story with a Final complication: "If the turkey is freshly killed do not try to serve it the same day, for you will end up with one stiff bird, rigor mortis having set in; give a freshly killed bird two days to relax."

When food writers begin sounding like morticians, a major advance for vegetarianism has been made. A circle is being closed. Marian Burros discussing the rigor mortis of Thanksgiving turkeys is not much different from George Bernard Shaw's discourse on "animal corpses" as he beheld the meat-filled plates of his dinner companions.

It isn't known whether this style of Shavian frankness helped cure England's cadaver consumers of their ghastly habit. It may even have had the opposite effect: the harder Shaw was to swallow, the more his dinner mates sprinkled meat tenderizer on their steaks.

But this is different from the frankness currently found in the food pages of U.S. newspapers. The skepticism of a Marian Burros is likely to turn citizens into nutritional vegetarians, as against the creation of ethical vegetarians, which was the goal of Shaw. To skip the turkey and go straight to the yams and peas is an attempt to dechemicalize one's body.

That turkeys and other meats have become so tasteless indicates that effectiveness of food technologists. In an earlier time, the birds, pigs and cattle that ended up on America's tables were tasty because they were vegetarians themselves. But now the animals are forced to ingest chemicals: to grow fatter faster.

To become a nutritional vegetarian is to seek an escape from the food technologists who attack the animals. The attacks, it is discovered, are really on us. A turn to healthy food is a turn away from death food.

The ethical and nutritional vegetarian is now being joined at the table by the economic vegetarian. Ewen Wilson, director of economics at the American Meat Institute, talks about "income elasticity": the more money a person makes, the more likely he'll eat meat. The less money, the less meat. "The demand for meat has been slow this year," Wilson says, "because of the economy. With a lot of people out of work,

families cut back on meat."

This is another circle making a full turn. Historically, man was a grain and berry eater. He moved against certain animals out of necessity. Plutarch writes in *The Eating of Meat*: "For my part I wonder what was the disposition, idea, or motive of the first man who put to his mouth a thing slaughtered and touched with his lips the flesh of a dead animal...Actually, the reasons those primitive people first started the eating of flesh was probably their utter poverty."

Today, with economic vegetarians increasing in number, the challenge for these involuntary abstainers is to resist the feeling of deprivation. We have been conditioned by the false message that vegetarians are weaklings and flakos, while the eaters of red meat—and, on Thanksgiving, white meat—are the real articles. Real, perhaps, but not so healthy.

The conditioning is wearing thin, especially since the meat industry has few defenders once the propagandists are removed. As Mark Braundstein, in *Radical Vegetarianism*, a new and remarkably intelligent book, asks: "What philosopher has written a convincing text for the cause of carnivorism? What poet has lamented the misunderstood lives of the butcher and executioner?"

None. Which is why the food writers are feeling less and less restrained in discussing rigor mortis on the dinner plate.

### 1. Animal Products

- A. Any part of the body of a once-living creature.
- B. Any substance or product produced by or within a living creature.
- C. Any product produced from or containing any part of, the body or products of a living, or once-living, creature.
  - A.
    - 1. Muscle Meats
    - 2. Organ Meats
    - 3. Other Body Parts
    - 4. Mixtures Containing Any of Above
  - B.
    - 1. Honey and Royal Jelly
    - 2. Eggs
    - 3. Milk, Cream
  - C.
    - 1. Butter
    - 2. Buttermilk
    - 3. Sour Cream
    - 4. Clabber
    - 5. Kefir

6. Cheese
7. Rennet
8. Yogurt
9. Whey
10. Ice Cream
11. Gelatin
12. Fish Liver Oil
13. Dessicated Liver
14. Bone Meal
15. Bone Marrow
16. Other Supplements Produced from Animal Sources
17. Lard

## **1.1 Animal Products Are Neither Safe Nor Desirable**

"The unfitness of certain substances for assimilative purposes is manifested by the anaphylactic symptoms that so frequently follow their use. Alimentary anaphylactic phenomena are confined almost exclusively to substances of animal origin. The more closely these animal substances resemble the human body in composition, the more frequently do they give rise to these phenomena. Thus flesh is the worst offender, eggs come second and milk is last." (Herbert M. Shelton, *The Hygienic System, Volume II*, p. 168)

The above eloquent indictment of animal products lays the groundwork for this lesson. Flesh foods have been dealt with in Lesson 32. Honey, eggs, dairy products, and various animal-food byproducts will be considered in this lesson.

Hereward Carrington (*The Natural Food of Man*, p. 167) says that such animal products are open to all those objections which might be urged against the use of flesh foods, only in a lesser degree. He says, however, that the objections to these products are less serious and that they are certainly to be preferred to meat—but he still concludes that there are weighty objections to their use.

We shall examine these objections in depth, so that the student may judge for himself whether, in truth, animal products in any form should be considered a safe or desirable part of the food program. I believe you cannot help but agree with Dr. Shelton that "Little can be said in defense of the use of animal foods except in instances of dire necessity."

## **1.2 Animal Products and Cancer**

Viktoras Kulvinskis (*Survival Into The 21st Century*, p. 228) says that though the high protein requirement for cancer growth comes, as a rule, from the dietary intake of animal carcass, it is also caused by eggs and dairy products.

He says that Dr. Szepeswal showed in experiments with laboratory animals that the incidence of lymphatic cancer and lung adenocarcinoma is as high in the mice receiving egg yolk as those receiving egg white. "In the animals of both groups the lymphoid system of the abdominal cavity is the first to be affected ... the adenocarcinomas of the lungs, whether caused by egg white or egg yolk, are very extensive, frequently destroying the whole lungs." (Szepeswal, J.; J. Proc. Exp. Biol. and Med., 1957, V96, 332 and P.S.E.B.M. Feb. 20, 1963, V112, P1073)

Dr. White found, through experiments with laboratory animals, that high dietary intake of cystine (a non-essential amino acid found in high concentration in animal protein) produced incidences of almost 100% of mammary tumors. (White, F.R. and White, J.; J. Nat. Cancer Inst., 4:413 (1944))

Dr. Babson observed that on a diet high in casein protein (the major source being the dairy products), some forms of cancer grew five times as fast as other forms. (Babson, A.L., Cancer Res., 14:89, 1954)

## 2. Honey And Royal Jelly

The honeybee's greatest usefulness is the pollination of endless numbers of crops. This occurs while the worker bee is engaged in its natural function of gathering nectar from flowers for the production of honey.

The nectar of the flowers is ingested by the worker bees and converted, by the addition of their own secretions, in special sacs in their esophagi, to the sweet, sticky substance we call honey.

This is regurgitated into the cells of the combs in the hives (built of beeswax by specialized worker bees), where it is aged and stored for future use—to feed the larvae and for subsistence in winter.

Bee honey is a complex substance, containing at least 181 known components. (*Honey, A Comprehensive Survey*, Edited by Eva Crane, MSc. PhD., p. 206)

Bee honey is composed chiefly of the simple sugars fructose (levulose), glucose (dextrose) and water; it also contains some more complex sugars (such as oligosaccharides and polysaccharides), some essential oils, several enzymes, various animal ferments (especially oxydase—oxydizing ferment) and acids. Honey also contains insignificant amounts of protein (amino acids and other protein constituents), vitamins and minerals.

Glucose crystallizes out of honey on standing at room temperature, leaving an uncrystallized layer of dissolved fructose. The fructose layer in crystallized honey ferments readily at temperatures of sixty degrees Fahrenheit or higher. Fermented honey is used in the production of honey wine or mead.

Honey to be marketed is usually heated by special processes to about 150 degrees Fahrenheit to dissolve the crystals, and is then poured into containers sealed against crystallization.

Bee honey is highly concentrated and stimulating, and is needed by the bees as fuel for their highly stressful and brief lives. Honey is an excellent natural normal substance for bees. Those who rob the bees to divert its use to humans are supplying an unnecessary and harmful substance. The popular belief that honey is a perfectly safe sweet for general and habitual use is a delusion.

Honey contains many acids which are injurious to humans. The sugar in honey is no less dangerous than any other sugars, refined or otherwise. The manite acid in honey renders its combinations with other foods even more injurious than ordinary cane sugar. (Dr. Shelton, *The Hygienic System, Volume II*, p. 168)

Honey is harmful to the digestion, the teeth and the nervous system. Honey, which is intended as a stimulant for bees, is also highly stimulating (and damaging) to humans.

The use of honey also causes an excess secretion of mucus. People with gastric or intestinal ulcers, or catarrhal conditions, should never use honey—neither should nervous and sensitive people succumb to its gustatory appeal—but they may have to learn the hard way.

The Hartbargers (*Eating for the Eighties*, p. 164) say that honey should not be fed to children. They say, "Many babies have trouble digesting honey and it has been shown to be a cause of botulism in infants. The Center for Disease Control in Atlanta recommends that honey not be given to infants one year old or younger."

Extravagant claims have been made for honey as a miracle cure. Various experiments have indicated antibiotic properties, which would, of course, also destroy friendly bacteria (such as those which aid in the digestion of food, as well as those which aid in the synthesization of Vitamin B-12).

These experiments and others for the treatment of burns and wounds, respiratory infections, digestive diseases, and malfunctions of the heart, are recounted in *Honey, A Comprehensive Survey*, pp. 260-263,

concluding, "In general, the use of honey is less likely to harm a patient than most other preparations, and on many occasions it has proved beneficial." This might be termed "damning it with faint praise," and is from the chapter on "The Biological Properties of Honey," written by a group of authors.

The actual nutritional value of honey is minimal, especially when compared to its potential for harm. Honey is poor in mineral elements and in vitamins. It has, about the same composition of minerals as white sugar, and is almost as devitalizing.

The clarifying process to make honey less cloudy removes thirty-five to fifty percent of the original vitamin content. More vitamins and minerals are lost by evaporation when the honey comes in contact with oxygen. Honey contains only insignificant (trace) amounts of iron, and not enough B vitamins for its own metabolism, and, when consumed by humans, robs the body of B vitamins and alkaline minerals.

At one point in *Honey, A Comprehensive Survey*, it is said that "all the knowledge and scientific research in this book endorses the 'goodness' of honey as a food for man." The book contains 608 pages and sells for \$52.50. Yet all that is really said in favor of honey as a food for humans has to do with its palatability, and the opinion that it is more "easily digested" and more natural than carbohydrates like, for example, sucrose. While stating that honey has valuable nutrients, it is admitted, perforce, that the amounts are so minute as to be insignificant, and concludes, "This need not surprise us, for honey is primarily a food for bees, not man."

These quotations are from the discussion of the "Nutritive Value of Honey," in the chapter on the "Biological Properties of Honey," written by a group of authors (pp. 265-266).

Dr. Jonathan M. White, Jr., on page 199 of the chapter on the "Composition of Honey," also says that "the levels of various vitamins are so low that they have no real nutritional significance."

## 2.1 Identity of the Acids in Honey

Much of the knowledge of honey acids has been obtained since the early 1950s. Formic acid was once thought to be *the* acid of honey, and it was thought that the last action of the bees in ripening honey was to add formic acid to preserve the honey.

It is now known that gluconic acid is present in honey in much greater amounts than all other acids; it is produced by the action of an enzyme in honey upon the dextrose in it. Except for gluconic acid, the sources of the various honey acids are not known. Many of them may already be present in the nectar.

Analysts seeking to measure the total amounts of the various acids in honey have encountered difficulties, leading to uncertainties or errors in the measurements. Consequently, information as to these proportions is not available.

Since I heard Dr. Alec Burton refer to some twenty or so acids in honey, many of which are harmful to humans, I have wondered which ones they are, and decided to research the subject and pass the information on to others who may desire it.

The following acids have been positively identified in honey:

acetic	gluconic	oxalic
butyric	lactic	pyroglutamic
citric	maleic	succinic
formic	malic	

The following acids have been identified in honey without rigorous proof of their identity, and it is considered that they are probably present:

- glycollic
- a-ketoglutaric
- pyruvic
- tartaric
- 2- or 3-phosphoglyceric
- a- or B-glycerophosphate
- glucose-6-phosphate

(from *Honey, A Comprehensive Survey*, Chapter Five; "Composition of Honey," by Dr. Jonathan M. White, Jr., pp. 169-170)

Dr. Shelton also refers to manite acid in honey. (*The Hygienic System, Volume II*, p. 168)

"Honey is not tested for pesticide residue levels, and no tolerance level has been established for pesticides in honey. Neither has there been a tolerance set for the many residual antibiotics which remain in honey, after bees are drugged, to enable them to function after they've been fed waste candy products (which incorporate dyes, colorings and other chemicals) to compensate for man's plundering of their hives." (Ida Honoroff, *Dr. Shelton's Hygienic Review*, March 1980)

Ida Honoroff also recounts an interview with Colonel Clair, president of Hawaii Bee Keepers Association, on radio station KPFM-FM in Southern California. Colonel Clair stated that all honey contains pesticide residues— "There'd be no way to avoid that from nectar collected from plants which have been sprayed by pesticides."

Of course, as explained in Lesson 32 ("Why We Should Not Eat Meat"), the pesticides are more concentrated in the honey than in the plants.

Colonel Clair feels that genetic failure among bees is the most dangerous threat of the modern practice of feeding them sugar and drugs, and various other practices, such as artificial insemination. The result is diseased bees, diseased honeycomb and diseased honey.

We don't need honey, but we do need the honeybees for pollination of our crops. Another impending disaster?

Most people should avoid concentrated sweets altogether, but dates, figs, raisins, dried bananas, etc., are much better adapted to human nutrition than a product manufactured by bees for their own use.

Dr. Alec Burton emphasizes the inadvisability of the use of honey. He related an experience he had with a terminal cancer patient, whom he had kept alive for a lengthy period by the use of a program of all-raw foods. The man was doing very well and was able to function and do some work. However, his weight was on the low side. His well-meaning relatives and friends, noting his too-slender appearance, urged him to take some high-caloried honey, to increase his weight. He ate the honey—and died.

"Now," Dr. Burton said, "I am not saying that honey causes cancer." He explained that this is simply an illustration of the fact that cancer patients can frequently be kept alive for long periods on a totally raw-food plant diet, and that *no deviations can be tolerated*. Honey, especially, with its many harmful acids, can be disastrous to such a patient.

Honey is not recommended for anyone's use. Its value is delusion, and its potential for harm is indisputable. Dr. Shelton does not recommend its use, but says that its vast potential for harm would be among those who are engaged in active outdoor work. Even for such people, it is almost impossible to find a food with which it can be favorably combined. If taken with fruits or grains, honey will cause fermentation. Honey also causes decomposition of protein foods, and the honey itself ferments from being held in the stomach long enough for the digestion of the protein. The least harmful combination, according to Dr. Shelton, is toasted bread. But he reiterates his warning against its use with any food.

Your best course would be to eliminate honey from your food program altogether—you don't need it as a sweetener if you are eating simple Hygienic foods. If you occasionally prepare a recipe that does require a sweetener, dates would serve a better purpose.

Dr. Vetrano says that the *occasional* use of honey will not do great harm—but it should not be used as part of the regular diet.

## 2.2 Royal Jelly

Royal Jelly is a highly nutritious (for bees) secretion of the pharyngeal glands of the honeybee, which is fed to the very young larvae in a colony, and to all queen larvae.

Obviously, this substance is subject to the same objections as those against honey. Royal Jelly is sold at high prices in health food stores as a "miraculous" and "nutritious" food for humans. Don't use it!

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > 3. Eggs

## 3. Eggs

Eggs are in the same category as flesh foods, since they are, of course, fowl in embryo. A fertilized egg is a fowl before it is born; an unfertilized egg is the product of a bird's sexual cycle.

Eggs from barnyard fowl (fertile eggs) are sometimes available in health food stores, and have some advantages over production-line eggs—but are hardly to be recommended as a food of optimal quality for humans. Even when the hens are allowed plenty of clean territory for running, adequate fresh, pure water, pure air and good grain—and cohabitation with the rooster—the resultant product (the egg) is apt to be less than optimal, even for non-vegetarians. The habits of the fowl are not clean—they will eat almost anything—eggs will sometimes taste of wild garlic which the hen has eaten.

On the other hand, production-line methods produce a particularly poor product, from the standpoint of nutrition and toxicity. Hens are fed arsenic to kill parasites and stimulate egg production.

About 95% of egg-laying hens are maintained in production plants. The routine conditions in egg production plants are certainly not conducive to producing eggs of high quality. Five fully grown hens in a twenty inch by twenty-four inch cage is routine in some hen batteries; some squeeze four hens into twelve inch by twelve inch cages. The hens cannot spread their wings or even turn around. Wire flooring often injures their feet, and hens have even "grown fast to their cages." (Victoria Moran, *Ahimsa*, April/June 1982, quoting from *Poultry Tribune*, February 1974)

Hens are de-beaked at one week and again at three to five months, to prevent featherpecking and cannibalism, brought on by the overcrowded conditions. Food and water are provided mechanically; conveyors remove eggs and waste. Fluorescent bulbs provide seventeen hours of artificial daylight to stimulate laying. The millions of eggs sold in supermarkets are the products of these "hen farms."

All eggs contain an excess of sulphur. Hereward Carrington (*The Natural Food of Man*, p. 173) says, "Persons who are subject to torpor of the liver would do well to refrain from the use of either eggs or butter; and those who have sound livers—and desire to keep them so—can take a hint."

Dr. Shelton, also, says that eggs should certainly never be eaten by one whose liver and kidneys are not in perfect condition. He says that children, invalids, inactive people and those inclined to constipation should especially avoid egg whites.

The raw albumen contains a toxic protein substance, avidin (a biotin antagonist). Biotin is one of the B-

complex vitamins. Avidin is inactivated by one minute of cooking.

Dr. Shelton says that raw egg whites produce in some stomachs almost deadly acids. He says that Vernon, Hetin and others have shown that raw egg white hinders the digestion of other substances.

"Bayliss, Professor of Physiology, University of London (*The Physiology of Food and Economy in Diet*) says that raw egg white contains some substance which, even in small amounts, hinders the action of the digestive fluids. Lemoine, a French authority, after careful study, says raw egg white contains a poison which damages the kidneys." (Dr. Shelton, *Volume II*, page 170)

Boxers, marathon runners and other athletes sometimes use whole raw eggs (blended with fruit juices) as "high-protein training food," and may give the impression that whole raw egg is an optimal food. You now know better!

Raw egg yolks are sometimes prescribed by Hygienic professionals as a temporary source of protein for people who are having digestive or other problems with the use of nuts as a protein source. Even though raw egg yolks are relatively innocuous and easily digested, their use should be confined to temporary emergency use, for many reasons (some already discussed and some additional factors still to be considered).

Dr. Virginia Vetrano (Dr. Shelton's Hygienic Review, February 1977, p. 136) says: "Taking a raw egg yolk in orange juice is not the best way to take eggs, if one is going to eat them. Eggs, being an animal food, decompose very rapidly if not digested soon. Taking them with an acid fruit such as oranges or orange juice, inhibits the secretion of gastric juice, necessary for normal digestion, and predisposes to putrefaction."

With further reference to the preoccupation of athletes with "extra protein," the following interesting comment appeared in a 1978 issue of the Journal of the American Medical Association. The Association's Department of Foods and Nutrition commented: "The ingestion of protein supplements by athletes who eat an otherwise well-balanced diet is of no use in body-building programs. Athletes need the same amount of protein foods as nonathletes. Protein does not increase strength. Indeed, it often takes greater energy to digest and metabolize the excess of protein. In addition, excess protein in the athlete can induce dehydration, loss of appetite, and diarrhea. Athletes DO have an increased requirement for *calories*."

In Lesson 32, in the discussion of salmonellosis, I mentioned that, if you open and eat a raw egg, there is the risk of bacteria from the outside of the shell contaminating the egg. (*Meat on the Menu*, Who Needs It? Raymond H. Woolsey)

Since some Hygienic professionals sometimes prescribe raw egg yolks as a temporary protein source for some debilitated individuals who have problems with nut proteins, I once experimented with their use (three yolks per week), but abruptly discontinued the experiment when they produced a goodly crop of hives—some on my face. I mentioned this experience in a previous lesson.

In view of this evidence, it would seem that it would be best to avoid the use of eggs altogether, if at all possible.

If, for any reason, it is desired to use eggs sparingly or temporarily, the following precautions should be borne in mind:

1. Egg yolks may be taken uncooked, preferably not in orange juice. If prescribed by a Hygienic professional, get his advice as to how to use them. In general, I believe it is recommended that they be taken alone.
2. Never use whole eggs uncooked, since the albumen is toxic.
3. If cooked eggs are ever used, they should be lightly cooked over low heat, preferably poached or coddled. A coddled egg is one that has been placed, in a covered pan, in water just below the boiling point (away from the heat source) for five minutes or so—long enough to slightly "set" the albumen.

4. If eggs are ever used, fertile eggs from a farmer or health food store are preferable to production line eggs. In addition to the use of arsenicals and the unspeakable conditions in the egg factories, which result in an unnatural and inferior product, production line eggs have also been considered objectionable on the grounds that they may have been kept in cold storage for long periods of time before they are sold. However, the executive vice president of the American Egg Board says that cold storage eggs are a thing of the past, that they go from hen to market rapidly, under well-controlled conditions, and that they are sprayed with oil to protect freshness. (*Better Nutrition*, June 1982, p. 65)

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > 4. Dairy Products

## 4. Dairy Products

### 4.1 Milk

All mammals take their mother's milk during infancy. After they are weaned, they are sustained by other foods—most humans, however, have been convinced that cow's milk is an ideal food for humans and should be used all through adult life. Recently, some medical men have been swinging away from this view, and blaming milk for a growing number of problems in children and adults.

There should be a transition period, during which a child eats other foods as well as nursing, but the time comes when milk is no longer needed. The use of dairy products by human adults is unique in the animal kingdom—man is the only animal that is never weaned—except, of course, for domesticated animals, who lap up saucers of milk.

The milk of each species is well adapted for the young of that species. Unpasteurized raw cow's milk is an ideal food for calves; it contains a growth factor intended for the maturing of a calf, but which causes excessive height in young humans, and complicated problems in adult humans, such as excess secretion of mucus, excess secretion of urine, constipation, diarrhea, bowel impaction, nausea, gas and discomfort, an increased blood pressure, edema, and numerous digestive and respiratory problems.

### 4.2 Milk for the Human Infant

Human milk is far superior to any other milk as food for the human infant. The chemical composition of cow's milk is different from that of human milk in many other important respects. Cow's milk is specifically adapted to the blood and chemical composition of the calf's body.

The rapid body growth and small brain of a calf require different nutritional elements than the human, whose body grows and matures slowly, who lives several times as long, and whose brain is the most rapidly growing and best-developed of all species.

Human milk contains lecithin, and an abundance of the amino acid taurine, both important to brain development. Cow's milk is deficient in both of these elements.

The milk of the nursing mother changes with the changing needs of the growing infant. Human milk is much lower in total protein than is cow's milk, and is sweeter and higher in carbohydrates. The types and amounts of fats, vitamins and minerals also are radically different.

In the preparation of the infant's formula, the cow's milk is usually diluted with water and sweetened to lower the excessive protein and provide supplementary carbohydrates.

The protein content of human milk is about one-third as much as in cow's milk, and is mostly albumin—

while the protein in cow's milk is mostly casein, which forms large, tough, dense, difficult-to-digest curds which are adapted to the four-stomach bovine digestive apparatus. Mother's milk forms very small, soft curds which are easily digested by the infant.

The following comparisons are listed in Composition of Foods, Agriculture Handbook No. 8:

	Human Milk U.S. Sample (100 grams)	Fluid Whole Cow's Milk (Pasteurized and Raw—3.7 per cent Fat) (100 grams)
Protein	1.1 grams	9.5 grams
Carbohydrate	3.5 grams	4.9 grams

Human milk contains much more (than any other milk) of the two amino acids, cystine and tryptophan, characteristics which render it superior for the human infant. Cow's milk is deficient in iodine, iron, phosphorus and manganese. The minerals in mother's milk are adequate for infants, but inadequate for adults.

Milk is splendid as the sole food for mammals during the period of their most rapid growth. A baby will ordinarily double his or her birth weight in 180 days with no other food.

Of course, mother's milk can be impaired by the diet of the mother. Many cases of colic (gas and constipation) in babies are "miraculously" cured when the mother stops eating eggs, meat and other animal foods.

If a mother does not have enough breast milk, she should give the child what she has and supplement it. The question is—with what? This question is of even greater importance, if it is not possible to nurse the infant at all.

It cannot be too strongly emphasized that the infant should, even at very great cost, be nursed during the initial period, for as long as possible. Breast milk contains hormones needed by the infant, and contains white blood cells which protect against infections, intestinal disorders and respiratory diseases; and this protection extends into later life. The yellowish, watery fluid (colostrum) secreted from the breast during the first few days of nursing has an especially vital protective role.

Bottle-fed babies are much more susceptible to allergies. They contract the so-called "contagious" diseases more than twice as often, and enlarged tonsils and adenoids are much more common among them.

Repeated evidence from Europe during the wars in 1871, 1914 and 1917, revealed that when no cow's milk was available, and the infants had to be breast-fed, the infant death rate dropped.

The nursing period of mammals varies according to the rate of their growth and maturity. Human growth is slowest and the nursing period should be longest. A baby should be nursed for at least nine months, and, if possible, up to two years, or even longer. Of course, the mother must eat correctly, exercise, and rest adequately. Green salads are of prime importance for the production of a good milk supply, and the nursing mother will need more protein. She should also slightly increase her consumption of distilled water to maintain her liquid requirement. Fresh, juicy, uncooked fruits will also provide additional liquid.

When the mother does not have sufficient milk, or when it becomes impossible for the mother to continue nursing, what is the best substitute? The old-fashioned "wet nurse" idea was the best—a substitute nursing mother.

Many vegans and Hygienists maintain that adequate infant nutrition can be maintained on vegetable

milks, such as soya, sesame, and nut or seed milks. These vegetable milks are also sometimes used when a baby is "allergic" to, or unable to digest or utilize animal milk.

However, it may be necessary to use animal milk for some babies. Dr. Alec Burton says that, if human milk is not obtainable, infants should have the milk of another animal, because they must have galactose, which is found in combination with glucose in milk sugar, and just does not exist in the plant kingdom. In this case, goat's milk is sometimes used, since it forms a smaller curd than cow's milk, and is therefore easier to digest, and does not have the excess growth factor. Also, it is somewhat easier to obtain goat's milk that is not pasteurized, from a goat that has not been fed drugs and antibiotics. Goat's milk is, of course, subject to some of the same objections as cow's milk.

It has been pointed out that practically no breast-fed infants die of "sudden infant death syndrome." Authors Geoffrey Marks and William K. Beatty note that telling evidence has been accumulated implicating a deficiency of selenium or Vitamin E in this syndrome. Human milk contains up to *six times* as much selenium and twice as much Vitamin E as does cow's milk, which contains even less when diluted for infant feeding. Marks and Beatty caution that this cannot be remedied by supplementation, because the tiny tract amounts of selenium required (or safe) leave no room for experimentation. (*The Precious Metals of Medicine*, Charles Scribner's Sons, New York, 1975)

In 1979, the nutrition committees of the American Academy of Pediatrics and the Canadian Pediatric Society issued a joint report, strongly favoring breastfeeding. They said that there are some things in Nature that simply cannot be duplicated, and gave the following reasons:

1. The fats obtained from human milk are more easily absorbed by the human infant than those found in cow's milk.
2. The cholesterol in mother's milk serves a valuable purpose in the development of the infant.
3. The protein in mother's milk is a near-perfect source for infants—much better than cow's milk.
4. Infants are able to absorb about 50% more iron from mother's milk than from cow's milk. Infants on cow's milk for extended periods are at risk for iron deficiency, whereas full-term breast-fed infants receive sufficient iron from mother's milk until their birth weight has tripled.
5. Mother's milk also provides important protective factors not available from any formula. Two substances, lactoferrin and transferrin, prevent potentially harmful bacteria from growing in the intestinal tract. In addition, the infant is provided with important immunities by a fluid (colostrum) secreted by the breast during the first few days following birth. Finally, breast milk contains lysozymes, enzymes that attack and break down harmful bacteria, as well as a substance known as the "bifidus factor," which promotes the growth of protective bacteria in the infant's body.

Pertinent to the subject of errors and abuses in the feeding of infants is an article by Rep. Morgan F. Murphy (D-III.) "Formulas Harm Third World Infants," (*Clearwater Sun*, p. 9A, 10/2/79): "About two million babies in the world's developing nations are suffering from what pediatricians call 'bottle baby disease.' It's largely the result of an aggressive marketing campaign waged by infant formula manufacturers who want to increase sales in Third World countries.

"As a result, many mothers have needlessly given up breastfeeding to feed their babies an infant formula that is often diluted or contaminated, causing malnutrition, intestinal infection, pneumonia, dehydration—and sometimes death."

The article explains that, since birth rates in the Western World have been declining, the manufacturers decided to expand into new markets. Drug companies, eager to increase profits through diversification, have acquired infant-formula companies. The companies found they could take advantage of increases in population in developing nations.

They promote their product through radio, newspapers, magazine and billboard advertisements, distribution of free samples, and offering gifts or money to health professionals to induce them to promote infant formula. These Third World countries now spend more than six hundred million dollars a

year on infant formula, about twice what the U.S. spends.

This has produced serious problems. The formula is very costly for those with low incomes, causing mothers to dilute the formula to make it last longer. Result: malnutrition. Because of lack of refrigeration and other conveniences and knowledge, the formula often becomes contaminated and the child gets sick or dies.

The aggressive and misleading promotion of the product causes many women to believe that breastfeeding is less than adequate. "Cruelly, in the time it takes to use up the free samples, a woman's secretion of milk may have become difficult or stopped altogether."

The article concludes: "The promotion of infant formula raises doubts in nursing mothers, whose anxiety then inhibits the flow of their milk. In point of fact, as noted by the organization Clergy and Laity Concerned, a mother's milk is free, always available, sterile, the right temperature and contains all the nutrition a child needs in the first four to six months of life."

### 4.3 Modern Methods of Milk Production

Present-day methods of producing milk involve the threat of milk from unhealthy animals, poor sanitation, poor methods of pasteurizing and handling bulk supplies, and drugs, including hormones and antibiotics, in practically all dairy products.

A cow normally would secrete enough milk to nurse her calf, about two hundred pounds of milk a year. Today she is allowed to nurse her calf for only three days, and has been developed into a milk machine, becoming pregnant often enough (a calf every year) to continue the secretion of milk, and fed and maintained for maximum milk production—up to 15,000 pounds of milk per year.

An Associated Press Report (printed in A.C. Press January 1, 1978) cites an article in the farm magazine, *Wallace's Farmer*, to the effect that dairy cows are now becoming "flabby, heart-disease prone" due to the unnatural living conditions on dairy farms; "confined to inactive lives of eating, drinking, resting, being milked, and producing one calf a year."

Researchers of the United States Dairy Association have come up with a "jogging program" consisting of a mechanical exerciser that keeps the animals walking at a controlled pace, while moving tailgates push the cows around a fenced ring. Some of the cows cooperate, some don't. (Ahimsa, Oct/Dec. 1977)

I am not sure whether the predominating factor in the preceding paragraph is its "humor," its pathos, or its asininity. Would it be too simple to just turn the cows out to pasture, letting them walk back and forth from the barn to the pasture, and letting them walk, run, jog, play, or just be—and relieve them of at least part of their confinement and *slavery*—and improve their health, in the process?

Overfeeding of cows on rich fare to constantly produce unnaturally large quantities of milk, forced long periods of milking, and the other circumstances of their slavery, are a drain on the organism. The cows become weakened and diseased, and they are then given massive doses of antibiotics, some of which can be found in the milk.

Dr. Alec Burton (Dr. Shelton's Hygienic Review, July 1974, p. 253) says that milk has become more of an excretion of the cow than a secretion, that many drugs, including antibiotics, are present in the milk, and that practically all milk today contains traces of penicillin.

Milk also contains concentrations of pollutants from the environment, such as DDT and radioactive Strontium 90.

"University of Wisconsin researchers Philip Bushnell and Hector De Luca have found that the lactose in milk facilitates the absorption of lead, which is, of course, toxic. Increased lactose consumption led to increased lead absorption and more lead in tissues studied." (*Vegetarian Living*, published by The Vegetarian Association of America)

Vegetarian Living also notes, "Researchers at the Wellcome Research Laboratories in Research Triangle

Park, North Carolina, have found two to five hundred nanograms of morphine in milk they tested. Pedro Cuatrecasas and Eli Hazum made the findings, based on immunological, pharmacological, biological and chemical test series."

#### 4.4 Pasteurized Milk

Whatever virtues raw milk may possess are seriously damaged by pasteurization. Heating the milk makes it even more difficult to digest and causes chemical and physical changes that destroy much of whatever nutritional value would have been available in the raw milk. The casein is coagulated and toughened, the vitamin and mineral components are spoiled and made unavailable to the body, and the lactic acid bacilli (beneficial intestinal flora) are destroyed.

In addition to pasteurization, milk is subjected to other processes, all of which impair its value; It is homogenized (so that the cream cannot be separated from the milk), sterilized and otherwise treated to render it "safe." Even though it is illegal, milk is regularly adulterated, and the adulteration is never put on the label. This is a violation of the Pure Food and Drug Act, but the dairy industry remains free of persecution. (Dr. Shelton, *Volume II, The Hygienic System*, p. 174)

Dr. Shelton says, "One of the most common adulterations put into milk are the so-called 'alkalinizers.' These are used most during the summer months to mask the taste of the milk produced by the growth of the bacilli in it. This enables the milk industry to sell old milk as 'fresh milk'."

#### 4.5 Raw Milk From Healthy Cows (?)

Unpasteurized milk is illegal in most states. Certified raw milk is available in some states. Dr. Shelton says (*Volume II*, p. 174), "Certified milk, produced by cows kept in sunless barns and fed on dry goods, is an especially inadequate food."

Raw milk from Farmer Brown's cow, Betsy, who grazes on an unsprayed pasture, and where immaculate standards of cleanliness are maintained, is probably the best obtainable.

But many people (children and adults) experience quick reactions when *any* milk is consumed. Excess secretion of mucus is quickly initiated, causing frequent colds, tonsillitis, bronchitis and asthma. Milk has also been a factor in the development of coronary artery disease. These and other problems (such as constipation, diarrhea, tetany) are inherent in the liberal use of the milk itself (even raw milk) and many people who use only small amounts of milk still suffer respiratory and other problems, which often, miraculously disappear when milk is eliminated in the diet.

Many people lack the enzymes lactase and rennin, necessary for the digestion of milk. Some adults who have used milk regularly all their lives may still be able to secrete these enzymes to some extent, and demonstrate no overt reactions when they drink milk (which does not, per se, prove that the milk is an optimal food for that person).

Lactose (milk sugar) comprises about 40% of the calories in breast milk, and about 30% in cow's milk. Lactase catalyzes the conversion of lactose, a complex carbohydrate, into the simple sugars, glucose and galactose, which can then be utilized by the body. Humans who are deficient in this enzyme have difficulty in utilizing dairy products, especially milk. They may suffer pain, nausea, vomiting, diarrhea and other problems.

This deficiency is very common in Japanese and Chinese people, and also exists in many blacks. Many children of all races have this deficiency, and handle milk poorly.

E.L. Cole, Jr., M.D. (*St. Petersburg Independent*, May 20, 1974) said, "Since so many children are allergic to milk, and because of the fact that 10% of the white population and 40% of the black population have a lactase deficiency, this raises the question of whether or not it should be eliminated from the school lunch program."

Neil Solomon, M.D., in a more recent article (*Clearwater Sun*, June 25, 1981) said that "from 60% to 90% of black adults and members of other ethnic groups are lactose intolerant, compared with 5% to 15% of white adults." He said that there are relative degrees of lactase deficiency, and the majority of persons are able to tolerate some small amounts of milk without becoming ill.

Rennin is a milk-coagulating (curding) enzyme which is secreted by glands in the stomach, and it is important in the digestive processes of infants because it prevents the too-rapid passage of milk from the stomach.

Rennin tends to diminish at about two years of age, when the baby has a mouth full of teeth, and when the salivary glands of the mouth begin the secretion of the enzyme ptyalin (alpha amylase) which is necessary for starch digestion. Intestinal starch-digesting enzymes also begin secretion at this time. These phenomena appear to signal the time for weaning and feeding solid foods. Rennin usually continues to be secreted in decreasing amounts for the next three or four years, for a transition period from the milk of infancy to solid food.

Dr. Shelton (Dr. Shelton's *Hygienic Review*, August 1969, p. 275) says, "Even in early childhood, when there is still a supply of rennin in the stomach, taking flesh, eggs or other protein at the same meal with milk will tend to result in the secretion of a highly acid gastric juice that will destroy or inactivate the rennin and interfere with or retard milk digestion; hence the wisdom of our rule: *Take milk alone or let it alone.*"

People who lack rennin or lactase may be able to tolerate dairy products which have already been clabbered or coagulated—such as clabber, yogurt, buttermilk or cheese—but have problems when they try to drink milk. Dr. Shelton says that Berg and others have noted that adult organisms handle sour milk more efficiently, the characteristics of the milk having been greatly altered by the ferment of the bacteria. (Dr. Shelton's *Hygienic Review*, August 1969, p. 276)

The thymus gland, which also has a function involved in the digestion of dairy products, reaches its maximum development during early childhood, and usually degenerates and becomes vestigial in adults.

The protein and fat of cow's milk is so constituted that the enzymes of the human digestive tract fail to digest it completely, so that some of the elements are absorbed intact and cause trouble. (Dr. Burton, Dr. Shelton's *Hygienic Review*, July 1974, p. 253)

Sylvester Graham, early pioneer in Natural Hygiene, found that physical workers of various kinds—farmers, mechanics, etc., were more vigorous and active and had more endurance if they ate only plant foods and used no milk.

"In the earlier editions of his 'The Newer Knowledge of Nutrition,' before he became a highly paid consultant on nutrition to the National Dairy Products Co., Professor E. V. McCollum stressed the fact that milk is not an essential in the diet of man. He pointed out that the inhabitants of southern Asia have no herds and do not drink milk. Their diet is made up of rice, soy beans, sweet potatoes, bamboo sprouts, and other vegetables. According to Professor McCollum, these people are exceptional for the development of their physique and endurance, while their capacity for work is also exceptional. They escape skeletal defects in childhood and have the finest teeth of any people in the world. This is a sharp and favorable contrast with milk-drinking peoples. The professor found it expedient to delete these facts from all editions of his work published subsequent to his becoming consultant to National Dairy." (Dr. Shelton, *Volume II*, p. 172)

The claim that milk is a protective food and that it will help bone development and prevent tooth decay has been demonstrated to be a fallacy. We are told that milk is a major source of calcium and if we don't drink milk, our teeth will fall out and our bones collapse, and most people buy these ideas, hook, line and sinker.

## 4.6 The Truth About Calcium

"The calcium in cow's milk is of too crude a nature to be easily assimilated by the more delicate, subtle human organism. Frequently, the coarser calcium attracts and absorbs the finer calcium in the human cells, robbing them of what little they had." (Ian Rose, *Faith, Love and Seaweed*, quoted in "Feeding Vegan Babies," Freya Dinshah, Ahimsa, Nov.-Dec. 1974)

This may be one explanation for the fact that tetany (muscle cramps) frequently follows the ingestion of milk. Some years ago, I drank three glasses of "good, raw milk" in one day, and experienced horrible muscle cramps in my hands, feet and legs.

My sister was a milk drinker, drinking several glasses a day all through her life, yet she lost all her teeth when she was in her early fifties. Although she drank pasteurized milk, this result was inherent in the milk itself (even raw), since the coarser calcium of the cow's milk robs body calcium.

Calcium is abundant in plant foods and a good Hygienic diet provides many times the required amount of calcium, in better form, and more readily utilized by the human organism.

The late Henry C. Sherman, Ph.D., Sc.D., formerly professor of Chemistry, Columbia University (*Essentials of Nutrition*), said that the dark green leaves are a prime source of calcium, *well utilized in nutrition*.

"Calcium is not Cowcium," says Vegetarian Living (published by the Vegetarian Association of America). There are many nonanimal foods in common use among Hygienists, each of which is as rich in calcium as cow's milk, if not richer. Some of these are sunflower seeds, dried figs, pistachio nuts, Brazil nuts, filberts, almonds, kale and other greens; and the calcium in these plant foods is readily available to the human organism, without stress and threat.

Natural sunlight (Vitamin D) is vital to calcium absorption. Foods high in oxalic acid (such as spinach, chard, beet greens, chocolate, coffee) interfere with the absorption of calcium. Wheat bran (a fragmented food) inhibits the absorption of calcium. Such unnaturally large amounts of fiber can impair the body's ability to absorb calcium and other important minerals. Natural sources of fiber (with few exceptions, some of which have already been mentioned in earlier lessons) don't interfere with the assimilation of calcium and other nutrients. (Harland, Barbara and Hecht, Annabel, "Grandma Called It' Roughage"—FDA Consumers Publication 78-2087, U.S. Department of Health, Education and Welfare, July/August 1977)

Be sure to note and differentiate among the various dark green leaves. Dark, leafy green vegetables contain considerable amounts of calcium, but they also contain varying amounts of oxalic acid. During food digestion, oxalic acid combines with calcium and forms an insoluble compound, calcium oxalate, so that the calcium *passes out of the body without being absorbed*. Those greens which contain large amounts of oxalic acid are therefore poor sources of calcium, since most or all of their calcium is lost to the body. They may even rob the body stores of calcium obtained from other foods. The "good guys" are romaine, buttercrunch and leaf lettuce; kale, broccoli, Brussels sprouts, cabbage and collard. These vegetables contain significant amounts of calcium and negligible amounts of oxalic acid. In kale, broccoli and collard, calcium exceeds oxalic acid by a ratio of forty-two to one. Beet greens, spinach and Swiss chard have up to eight times as much oxalic acid as calcium. (*Prevention*, June 1980, p. 40)

It is worthwhile to take the time and effort to understand the importance of calcium, and its sources. Calcium is needed for proper bone and cartilage formation, for proper blood clotting, for muscle functioning, for hormone activation, for tissue formation. Calcium influences capillary permeability.

Calcium deficiency can cause headaches, heart palpitation, listlessness, sleeplessness, and affects nerve function and thought processes. Adequate calcium supplies can help to keep cholesterol levels in the normal range. Calcium activates numerous enzyme systems and normalizes the contraction and relaxation of the heart. It is essential in the maintenance of the delicate acid-alkaline balance.

During the years of growth, 99% of the available calcium is utilized in the formation of bones and teeth.

Subsequently, extra supplies of calcium and other minerals are stored in the bones and drawn upon in emergencies for balancing the body chemistry. A small percentage of the body's calcium is found in body fluids and tissues.

June M. Wiles, whose research on this subject is summarized in her excellent article, "Good Nutrition," (*Independent Press*, September 10, 1975) says, "It is unfortunate that a majority of our medical practitioners, when seeing "too much" calcium in blood studies will take the patient off calcium instead of seeking to find why an excess is present. There is hardly such a thing as "too much," especially the way we Americans eat."

She says that it is probable that a *deficiency* of calcium may exist, because the body is incapable of retaining it. We must understand that other nutrients influence the absorption, utilization and stability of calcium. Calcium will be rejected by the body if Vitamins A, D, C, magnesium, phosphorus and dietary protein are absent or deficient.

Ms. Wiles says, "If more physicians would check first for these deficiencies before withdrawing calcium, I dare say the rate of individual recovery would increase 100%."

A January 1981 *Prevention* article (p. 65) gives an interesting table of the nutritional value of four types of lettuce:

(100 grams or one serving)	Vit. A. (IU)	Vit.C (mg.)	Calcium (mg.)	Iron (mg.)
Butterhead lettuce (Boston, Bibb)	970	8	35	2.0
Romaine lettuce	1,900	18	68	1.4
Crisphead lettuce (Iceberg head lettuce)	330	6	20	0.5
Loose-leaf lettuce	1,900	68	18	1.4

They are nearly equal in other vitamins, minerals, protein and carbohydrates.

"Peas and mung beans contain calmodulin, a protein which works with calcium in such vital processes as activating enzymes in the red blood cells, skeletal muscles and the brain, as well as controlling muscle and nerve action, blood clotting, cell mortifying and cell membrane functions." (*Vegetarian Living*)

As we have so often emphasized, those who utilize an intelligently planned Hygienic diet, consisting mostly of whole, raw foods, need have no concern about deficiencies of any nutritional elements.

#### 4.7 Don't Drink Milk

Carrington says, (*The Natural Food of Man*, p. 170), "Even if an animal is perfectly healthy, the milk partakes of the nature and general character and composition of the animal's body," and while this may not be actually diseased, it is doubtless in a more or less depraved condition—as are practically all domesticated animals, particularly the cow—during the confined period of winter. And the milk, being a secretion, naturally takes on the conditions of the body of the animal—as would any other secretion.

Carrington says, "Indeed, Professor L.B. Arnold, an excellent authority on all dairy matters, says, 'Milk is the scavenger of the cow's body.'"

Cow's milk is usually used by adults as a beverage—it is not a beverage, but a food. In its raw state, unpolluted and unprocessed, it is an excellent food for calves.

It is emphatically not recommended for human consumption, especially adult humans.

#### **4.8 A New Use For Milk**

David Reuben, M.D. (*Everything You Always Wanted To Know About Nutrition*, pp. 161-162) says: "Someone in Washington, D.C., once got the bright idea that black African tribesmen would eat better if we sent them some of our powdered skim milk. The Africans gratefully accepted the wonderful powdered skim milk from their American benefactors—they accepted tons of it, in fact. They mixed it with water and tried to drink it. They got sick. They tried to drink it again. They got sicker. They stopped drinking it.

"But they were poor people, accustomed to making the best of a hard existence. The powdered skim milk...did not go to waste....That particular tribe has the whitest mud huts of any tribe anywhere. Each day little black boys dip their brushes in fabulously expensive high-protein skim milk and carefully whitewash the brown mud walls of the family dwelling."

*Vegetarian Living* says, "Humans who have not had milk as part of their hereditary diets do not have this inherited ability to deal with such an unnatural diet, and are lactose-intolerant. Most blacks, Jews, Southern Europeans and Orientals, as well as many Latin-Americans, are lactose-intolerant. Powdered milk sent as food aid to Latin America ended up being used to whitewash the houses there."

#### **4.9 Cream and Butter**

Cream is essentially an animal fat, containing very little of the protein and other elements of milk. If consumed in large quantities, it would, in some respects, be even more injurious than milk. But, taken in very limited quantities, as it usually is, it is probably much less harmful than fats from the bodies of slaughtered animals. It is, of course, subject to most of the same objections as milk.

Butter is also an animal fat which is to be preferred to fats from the bodies of animals. Consumed in limited quantities, it is generally not extremely harmful. Again, it is subject to many of the same objections as milk.

Some Hygienists who are not on totally raw food diets use limited amounts of unsalted butter—and a few may also use some cream. Both cream and butter are burdensome to the digestion, and cause an excess secretion of mucus. Use should be sparing—or *nil*.

#### **4.10 Clabber, Kefir, Buttermilk, Sour Cream, Cheese**

These are subject to many of the objections given for milk. As previously indicated, some adults are better able to tolerate "sour milk" which has been coagulated or acted upon by the ferment of bacteria. The question is: Should these fermented foods be used, or should they be considered "spoiled" or "rotten" milk? And is there a difference between naturally soured milk and milk soured by the introduction of a culture?

Raw milk contains natural lactic acid bacteria which, if left alone at room temperature, will grow and sour the milk. It is not always successful, however, since fluctuating temperatures may prevent proper clabbering (resulting in an odoriferous, unpleasant product). Most homemade clabber is made by introducing a culture, and commercial products such as sour cream, buttermilk and cheese are, of course, cultured.

Kefir is a slightly effervescent acidulous beverage of low alcoholic content made chiefly in southern Russia of cow's milk that is fermented by means of kefir grains. A kefir grain is a small mass resembling a tiny cauliflower, occurring in kefir, containing casein and other milk solids, together with the yeasts and lactobacilli that cause the characteristic kefir fermentation, and serving as a starter to induce this fermentation when introduced into fresh milk.

Kefir may be said to resemble clabber or yogurt. It is a dairy product, and subject to the same objections as all dairy products, except that it, like other clabbered products, may be better tolerated by adults than milk. It is also subject to the same objections as all fermented products.

Years ago, a friend gave me a kefir starter, and I made it a number of times. I found it somewhat unsatisfactory, since the grains must be lifted from the sour milk and saved for the next batch. The process of removing the grains broke up the custardy consistency into a messy, unappetizing product.

We also did not care much for the taste. I was rather relieved when the starter was lost when we moved to Florida.

When we ate some meals at Dr. Esser's fasting retreat in 1967, he served clabber, sour cream, butter and cheese (sparingly). The clabber was homemade, using commercial sour cream as a starter; the butter was unsalted; and the cheese was an excellent-tasting ricotta. I don't know what their practice is now. I have heard Dr. Esser say, at American Natural Hygiene Society Conventions, that he considers cheese to be a useful supplementary source of protein.

Some Hygienists are convinced that limited amounts of cheese should not be ruled out as a supplementary source of protein (where needed or desired); cheese and butter are usually included in the food items available at the American Natural Hygiene Society Conventions, for those who desire these foods.

It is usually recommended that cheese (if used) should be one of the following:

*First Choice:* Homemade cottage cheese, unsalted, made from unpasteurized milk.

*Second Choice:* Unsalted cheese, available in health food stores, made from unpasteurized milk, using vegetable rennet.

*Third Choice:* Ricotta cheese or cottage cheese marked 100% natural and containing no preservatives (we hope it's true), available in many supermarkets.

*Fourth Choice:* Unprocessed cheddar or other mild cheeses marked 100% natural, or with labels which do not list any additives (although that does not always guarantee it is free of additives). Read the labels.

The last two groups would presumably all be made of pasteurized milk, and would also contain some salt. Occasionally, unsalted cheeses are available in supermarkets.

## **4.11 Rennet**

This substance, from the stomach of a newborn calf, is used in the processing of most commercial cheese. Sometimes rennet is obtained from the stomach of other newborn animals (e.g. hogs).

Some companies produce rennet less cheeses, which are made with vegetable coagulants. These cheeses are usually available in health food stores. Not all varieties of cheese can be produced with the vegetable coagulants. It is my understanding that it is not possible to produce the large holes in Swiss cheese unless the animal rennet is used.

## **4.12 Yogurt**

I did not include yogurt with the other fermented dairy products because of some special comments that are pertinent to it alone. It is, obviously, also subject to the same objections given for other dairy products (unfermented and fermented), with the same stipulation that adults are better able to tolerate products which have already been coagulated.

Lactobacillus acidophilus bacteria, lactobacillus bifidus bacteria, and coli bacteria are normally present in the digestive tract of humans. They are sometimes called "friendly" or "beneficial" intestinal flora, and are necessary for human symbiosis and the proper absorption and utilization of foods. These natural intestinal flora can be adversely affected (or destroyed) by taking antibiotics.

There has been some evidence that using yogurt cultures for prolonged periods can also adversely affect the natural intestinal flora, or impair the body's own ability to foster the development of such natural friendly bacteria. One research team at Johns Hopkins Hospital even discovered a relationship to cataracts.

Nutrition researcher Gordon F. Fraser, B.Sc. ("The Yogurt Scare Is For Real," *Let's Live Magazine*, August 1970) says, "Most commercial yogurts contain harmful bacteria, of other than human origin, called bulgaricus bacillus; these die out in the human intestinal tract, and do a great deal of harm to the system before dying."

He says that this culture dominates and destroys the beneficial, necessary intestinal flora which help to utilize food particles, keep down pathogenic germs, stimulate peristalsis, detoxify and create a soft, smooth stool. Their main function is to aid in the nourishment of the cells and speed up the utilization of food.

Fraser maintains that negative reactions do not occur if the correct culture is used, provided it is not perverted in some way—by mixing with other cultures, or by the use of artificial additives, flavors, chemicals, etc. He says, "There is available in health food stores the correct and helpful bulgaricus culture which has not been altered by such conditions." It is a liquid containing a natural live culture of lactobacillus acidophilus, the correct lactobacillus bulgaricus, lactobacillus caucasicus, lactic acid and yeast in milk whey, all of which help to maintain a healthy intestinal flora. He says that California's Aha Dena Certified Dairy and Walker-Gordon Certified Dairy in the Eastern United States use this product.

Does all this sound confusing to you? It certainly should make one uneasy about the regular use of any yogurt. Why risk inhibiting or impairing your natural intestinal flora? Why not, instead, stick to the Hygienic diet of all raw, or mostly raw, foods and have faith in your body's own ability to develop and foster its own beneficial intestinal flora?

#### **4.13 Whey**

Whey is the serum, or watery part, of milk (containing lactose, minerals and lactalbumin) which is separated from the thicker, or more coagulable, part (curd), especially in the process of making cheese.

The late J.I. Rodale (*Prevention Magazine*) repeatedly maintained that, while dairy products were harmful and "allergenic," the whey has none of the harmful properties, while retaining the "beneficial" characteristics of contributing to the body's beneficial intestinal flora. He therefore promoted and endorsed the use of whey tablets as a food supplement.

I tasted the whey which drips out of the clabber in making homemade cottage cheese, and did not find it to my liking. Whey is still subject to many of the objections against other dairy products. In addition, it is fragmented, and used to supply the body the beneficial intestinal flora which a healthy body should synthesize from a normal diet predominating in raw foods.

The regular use of whey as a food supplement may thus serve to inhibit the body's natural ability to provide these flora by making it unnecessary for the organism to function in this manner. Whey supplements are no more necessary than other supplements.

#### **4.14 Ice Cream**

This is the difficult one for many people. Should one take the Alcoholics Anonymous pledge of "not even once" or cater to our human frailty by occasionally indulging in homemade or so-called "natural" products? The best choice, obviously, is to divorce yourself completely from this temptress.

Regular commercial ice cream, with its twenty to thirty additives, is a particularly pernicious product. Some of the so-called "natural" ice creams may not be quite as bad, but, upon reading the labels, I found only one supermarket brand that contains no additives (except sugar and sometimes salt). At least the

law now requires listing these additives on the ice cream package—until recently it was not required.

Since the new law was passed, Farm Stores has discontinued advertising "natural" icecream.

Breyer's is the only supermarket ice cream I have found that actually contains no "additives" for most flavors (except sugar and salt). Their Buttered Almond Ice Cream actually contains only milk, cream, sugar, almonds, butter and salt. I believe I have seen some of their flavors that do not even contain butter or salt—just milk, cream, sugar and natural vanilla, fruit or nuts.

However, from the Hygienic point of view, the sugar is about as bad (or perhaps almost as bad) as the chemical emulsifiers and preservatives. And the milk and cream are subject to the same objections as for all dairy products.

Homemade ice cream may be a little better, because you can choose your own ingredients, such as unpasteurized cream or milk, and dates for sweetening, or even "ice cream" made without dairy products. But it is still a concoction to be avoided. There are some recipes for ice cream in Lesson 27—some using dairy products—and some without the use of dairy products.

Banana "ice cream"—made by freezing bananas and putting them through a Champion juicer (using the homogenizing blank)—is the best "substitute" for ice cream—not as good as eating bananas in their natural state, but not really harmful. It is as thick and "creamy" as ice cream.

If banana "ice cream" (other fruits may also be used) temporarily satisfies your nostalgia or craving for ice cream, it serves a good purpose. Hopefully you will eventually progress to the total elimination of such compromises from your food program.

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > 5. Gelatin

## 5. Gelatin

Gelatin is made from the skin, tendons, ligaments and bones of animals. It is considered an animal protein food, except that it is deficient in one essential amino acid, tryptophane. It has sometimes been recommended to people with problem finger nails, who eventually find that it not only doesn't help their nails, it also causes other problems, due to an excess of an unnatural protein which is unbalanced and incomplete in an important and destructive way.

This product should never be used. If it is ever desired to produce a gelatinized dessert for a party, etc., vegetable gelatin (agar) may be used. Better yet, serve something other than a gelatin dessert.

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > 6. Fish Liver Oil And Other Animal Food Supplements

## 6. Fish Liver Oil And Other Animal Food Supplements

(e.g. Dessicated Liver, Bone Meal, Bone Marrow, etc.)

The lesson on food supplements should eloquently refute the case for these substances. The items referred to above should be rejected both as animal products and as "pills" that promise much benefit, but deliver much harm.

I am including in this lesson Dr. Shelton's grave warning against the use of cod liver oil. Most modern food supplements include halibut liver oil instead (which is no better). Dale Alexander (*Arthritis and Common Sense*) touts cod liver oil as a universal panacea. I well remember forcing this repulsive grease on my own child, in the firm belief that it was beneficial and necessary (long before I knew about Natural Hygiene).

Dr. Shelton (Volume II, p. 175) says that Agduhr and Malmberg both came to the conclusion that cod liver oil is harmful to the heart, and is often responsible for death in children. Agduhr tested the oil on rabbits and Malmberg used children for his tests.

"Agduhr, working with Dr. N. Stenstrom, proved definitely by animal experimentation that cod liver oil produces pathological changes in the heart muscle. F. Hendricksen concludes, from his tests, that large doses may produce general cell degeneration throughout the body.

C.W. Herlitz, I. Jundell and F. Wahlgre, after conducting an extensive and elaborate series of experiments, showed that doses quite comparable with those given to children in ordinary practice, can produce considerable degeneration in the heart muscles. These men feel that the public should be warned of these dangers as well as of the dangers from radiated milk."

I am also including the following information relative to bone meal. "C.S.P.I., the Center for Science in the Public Interest, in their news letter, 'Environment and Behavior,' has warned consumers, especially children and pregnant women, to avoid bone meal supplements because of lead contamination. Lead ingestion by humans has been connected to kidney failure, anemia and nervous system disorders. Unborn and young children could suffer from mental and behavioral problems from even low lead absorption levels; higher levels would be worse." (*Vegetarian Living*)

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > 7. Lard

## **7. Lard**

Lard is obtained by rendering the fatty tissue of the hog. It is difficult for me to discuss lard in a restrained manner, because I find it so disgusting. It is a product of the worst of the meat animals, and it is the worst of the cholesterol-abundant, saturated fats. Since it is an animal product, it is included in this discussion, though I can't believe any students of Natural Hygiene would ever consider its use. (Vegetarians who eat bean dishes in Mexican restaurants should be sure they weren't cooked in lard, since this is often the case).

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > 8. None Is Best

## **8. None Is Best**

I hope that, as a result of this lesson, you will decide never to use animal foods in any form. If you should elect to occasionally use certain animal products which are somewhat less pernicious than flesh foods, be aware that less is better and none is best.

## 9. Substitutes For Substitutes

In the transition to a Hygienic diet, some people become concerned and disturbed about finding "substitutes" for animal foods—not realizing that the animal foods are the "substitutes"—a perversion of man's natural diet. It is not necessary to search for substitutes that look, smell or taste like the animal-source foods. In fact, you can get into worse trouble by preoccupation with such substitutes.

If you eat lettuce, tomatoes, celery, cucumbers—if you eat bananas, grapes, oranges, melons—if you eat sunflower seeds, pecans, almonds, walnuts—you know exactly what you're getting. These foods might not be organically grown, they might be sprayed, but they are in their natural form, they have not been adulterated, or robbed of their enzymes or nutritive value.

But if you eat manufactured foods, you really don't know what you're getting. All kinds of imitation foods are offered to the public—imitation cheese, non-dairy whipped topping, imitation eggs, imitation butter. If you don't want to be "ripped off," read the labels. Of course, much of the time the labels don't tell the whole story. Better yet, use foods that have not been changed, and therefore *need no labels*.

Beatrice Trum Hunter reports that meat substitutes labeled "textured vegetable protein" are manufactured through a textile-like process, spinning soy bean fibers that can be shaped into meatlike products. The drastic alkali treatment to which they are subjected reduces the protein value, and an amino acid derivative is formed which is toxic. Levels of sodium are very high, calcium and zinc are less available, and the iron is bound up in a form of low availability to the body. *The resultant product is much worse than meat.* (Beatrice Trum Hunter, "The Great Nutrition Robbery," National Health Federation Bulletin, August 1979)

If you want to use soy beans, use sprouted soy beans or Mung beans, or soak dried soy beans overnight and cook them. If you want to eat something that looks and tastes like meat, you'd almost be better off just eating meat itself, bad as it is, because the synthetic product is much worse. But the best plan would be to avoid the meat and the imitation meat products.

### 9.1 A "Synthetic" Calf

In 1965 the United States Department of Agriculture proudly announced a milestone: the birth of a calf from a cow reared on a totally synthetic diet—urea, corn starch, corn sugar, wood pulp, minerals and vitamins. The calf appeared normal at birth, and during the first fifteen days of its life it gained twenty-nine pounds. On the sixteenth day, it was found lying dead in its pen. An extensive postmortem examination failed to show the cause of death.

## 10. Reject Animal Products For Optimal Health

No animal products are necessary for optimal health. No imitations of animal products are necessary for optimal health. No deficiencies will be experienced on a Hygienic diet. There is a great danger of deficiencies in a diet predominating in animal foods and deficient in fresh fruits and vegetables. A horror

story appeared in *Better Nutrition*, September 1977, about a woman who had six operations before it was discovered that all that was wrong was subclinical scurvy, due to a diet deficient in fresh fruits and vegetables.

Experience the delights of a plethora of varieties of fruits, and the delights of good health. The green leaves of Nature and the little sunflower seed kernels are treasure chests of nutrition.

A diet predominating in animal foods is admittedly poor in calcium unless milk and cheese are used. Yet the calcium of milk and cheese has been shown to be the frequent cause of *calcium depletion* instead of a source of supplying needed calcium to the body. (See previous quotation from Ian Rose, *Faith, Love and Seaweed*.) We have also learned from Professor of Chemistry Henry C. Sherman that the dark green leaves are an excellent source of calcium, *well utilized in nutrition*.

Dark green leaves, such as romaine, kale, etc. are almost incredibly rich in vitamins, minerals, enzymes and hormones, and they contain small amounts of easily-assimilated protein of high biological value. They are also rich in chlorophyll, which has a close molecular resemblance to hemoglobin, and is thus Nature's blood-building element for all plant-eaters, including humans.

And the sunflower seed! No food is complete in itself, but the sunflower seed comes very close. Refer to Lesson 24 for details about the bonanza of nutritional elements sunflower seeds provide, including calcium and quality protein.

Previous lessons have shown the tremendous variety of plant foods to choose from and enjoy. So why in the world do we need to eat animals or animal products, when Nature has provided so adequately for our needs?

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > 11. Some Plants Also Should Be Rejected

## 11. Some Plants Also Should Be Rejected

It must not be forgotten that not all products or derivations of the plant kingdom are recommended for use as food: (cranberries, chard, beet greens, spinach - see Lessons on oxalic acid); coffee, tea, chocolate, etc. hail from the plant kingdom too; as do oleomargarine and other hard vegetable fats, all of which are *emphatically* not recommended.

It should also be remembered that foods or plant products should not be used as medicines. Your health food store's shelves abound with such "Miraculous cures" as apricot kernels, ginseng, etc. See the article "Plant Products and Effects" in this lesson.

When you abandon animal products, also bear in mind that you must judiciously select your foods from the plant kingdom, rejecting those which contain toxic substances in nutritionally significant amounts, and rejecting the use of foods or plants for medicinal or "curative" purposes. As you have learned, there are no "cures."

The only source of healing is your own body, and the only way you can help is by providing ideal conditions for the implementation of its own self-healing power. Such conditions are optimum during a fast, and the healing effect is consolidated and multiplied when the fast is followed by Hygienic eating and living.

## 12. Be The Best You Can Be

As health improves, the desire for animal foods, or imitations of (or substitutes for) animal foods will fade. The more knowledge one acquires, the less difficult the transition, and the more certain the attainment of the ultimate goal—to be the best you can be—the healthiest, the happiest, a fine example of Hygienic living.

## 13. Questions & Answers

### Why do some Hygienic professionals continue to utilize egg yolks and cheese?

It is a question of accepting a compromise solution to a difficult problem. Dr. Vetrano says (Dr. Shelton's *Hygienic Review*, January 1975, p. 116), "Most individuals have a difficult time adjusting to eating only nuts for protein and take an insufficient amount of protein at first." She is, of course, referring to people who are endeavoring to adjust to the Hygienic food program. She suggests adding green vegetables to the diet, since they contain small amounts of protein of high biological value.

Dr. Vetrano also says (Dr. Shelton's *Hygienic Review*, November 1974, p. 55), "The strict vegetarian diet is best for most people. There are occasional sick people with gastrointestinal problems who must temporarily be placed on milk (milk products—clabber or cheese), if they cannot take a fast of sufficient length for complete healing."

When Hygienic professionals suggest the use of egg yolks or cheese, it is usually with the hope and intention of providing supplementary protein to those individuals who are not yet able to accept, digest or assimilate an adequate supply of protein from the plant kingdom.

### Did the American Indians have a source of animal milk?

No. Indian children were usually weaned at about four years of age, and never again had milk. Cows were introduced into New England in 1624, but were seldom used for their milk at that time. "Cows were seldom milked at this time, being raised principally for their hides, secondarily for meat, and only incidentally for milk." (*Social Forces in American History*, A.M. Simons), (quoted by Dr. Shelton, *Volume II*, p. 172)

### What is the difference between Natural Hygiene and veganism?

A strictly Natural Hygiene food program is a vegan diet—that is, foods from the plant kingdom only. However, in actual practice, it is my impression that those who are known as vegans usually use grains (including whole grain bread) to a greater extent than do Natural Hygienists, and use more cooked food.

### Is there any Hygienic objection to the use of prepared soya milk fortified with Vitamin B-12?

Prepared soya milk is a manufactured product, quite far removed from the soy bean as it grows. The Vitamin B-12 used in this product is "synthetic" and non-animal, though it is made by the same bacterial process as occurs in the bodies of humans and other total-vegetarian animals. If you have misgivings about having enough Vitamin B-12, the product mentioned would be less objectionable than the Vitamin B-12 from animal sources (liver extract).

However, Dr. Vetrano firmly believes that it is not necessary to use such artificial methods. She has repeatedly seen Vitamin B-12 problems disappear due to fasting and a Hygienic program of living and eating.

### **What is the purpose of emulsifiers in foods? Food additives worry me, and I don't really understand most of them.**

To emulsify is to convert unmiscible substances into intimate mixtures (as oil and water). Emulsifiers, stabilizers and thickeners are the substances that make cream seem thick, keep the oil and vinegar in salad dressings from separating, and generally give a smooth, uniform texture to bread, bakery products, ice cream, puddings, shortenings. As Dr. Michael F. Jacobson points out in his book, *Eater's Digest*, some manufacturers use a recipe that automatically produces a food with satisfying texture and consistency. Other manufacturers of the same products rely on the above group of additives to cover up the fact that inferior ingredients or poor manufacturing practices make their product watery, lumpy or crystalline."

Hygienists need not be concerned about additives if they use whole plant foods, mostly raw, and avoid packaged foods.

*Eating May Be Dangerous to Your Health*, by Dr. Jacqueline Verrett and Jean Carper, gives details about various other additives in foods, and says that "there is overwhelming evidence that chemicals in foods can cause readily noticeable structural defects in the newborn, such twisted spines, shortened limbs, incomplete skulls, absence of eyes, cleft palates, web feet."

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > Article #1: Milk by Dr. Alec Burton

### **Article #1: Milk by Dr. Alec Burton**

Hygienists have always adopted the position that milk is for infants, *mother's milk* that is, and that this is the normal practice among all mammals. During the initial phase of life it is the invariable practice of all mammalian species to take the milk of their mothers following which they are weaned, and spend the remainder of their life sustained by other foods. Man, on the contrary, teaches that milk is an ideal food, essentially cow's milk, and that after mother has performed her nursing, the cow should take over. In his feeding of infants, man has produced all types of formulae and means to usurp the natural habit of breast feeding. Even in his feeding of other mammals as pets man is wont to include milk in their diet.

Many women regard breast feeding as culturally regressive and primitive, something one should abandon as quickly as possible. They say it ruins their figure, that their breasts become atonic and pendulous. Such remarks are unfounded and other factors are responsible yet seldom are considered.

It is normal in nature for the mammal to breast feed into the post dentition period, that is well past the time the infant obtains a mouth full of teeth. Not just a few teeth but all teeth. Species of apes nurse for six or seven months although their first teeth have appeared at the end of three months. With mammals, there is a wide variation in the transition period, weaning taking place in many over a long period of time.

However, should milk constitute an integral part of the diet after weaning? Is milk a normal food for adults? The answer to both these questions is an unequivocal no!

Milk and milk products such as cheese and yogurt are viewed with suspicion by hygienists. Yogurt has possibly more to commend it than the other milk products and undoubtedly the changes wrought in the milk by the bacterial activity in producing the yogurt mitigate several of the unsatisfactory features of milk.

What are the unfavourable attributes of milk? Today milk is very much a processed product. It is pasteurized, homogenized, sterilized and otherwise treated to render it 'safe.' All these processes impair its value.

Historically it is revealed that the primitive animal of some time ago used to produce some 200 pounds of milk a year. The 'modern' cow may produce up to 15,000 pounds of milk a year, seventy five times as much. How has this influenced the quality? Milk has become more of an excretion of the cow than a secretion, and many drugs, including antibiotics are present; practically all milk today contains traces of penicillin.

There is also strong evidence to indicate that the adult gastric juice does not contain rennin, an enzyme which initiates the digestion of milk and which is abundant in the infant stomach. The protein and fat of milk is constituted in such a way that the enzymes of the human digestive tract fail to digest it adequately; some of the elements are absorbed intact and cause trouble. Milk also contains a high content of the chemical cholesterol and has been a factor in the development of coronary artery disease. Many people observe the quick action taken by the body when milk is consumed; much mucus is secreted or diseases associated with mucous membranes, asthma, sinusitis, bronchitis, etc. are aggravated. Milk is said to be a 'mucus forming' food and whilst I don't favour this description, I do suggest that its presence in the body may be the occasion for greater mucosal activity.

Milk is often considered a major source of the vital element Calcium: if we don't drink milk, our teeth will fall out and our bones collapse, or some such nonsense. Calcium is abundant in nature. Most of the foods, fruits, vegetables and nuts we recommend are excellent sources of calcium. It would have to be a very poor diet indeed that did not supply half a gram of calcium daily. A good hygienic diet would provide in excess of one gram.

Milk forms no part of the normal diet of man after the period of infancy and therefore our advice is—don't drink milk.

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > Article #2: The Digestion Of Milk

## **Article #2: The Digestion Of Milk**

The first step in the digestion of milk is that of coagulating or curdling. Milk may be made to curdle by adding an acid to it, such as lemon juice or some other acid fruit juice or by the hydrochloric acid of the stomach. Normally, the coagulation of milk in the stomach of a young mammal is done by an enzyme secreted by glands in the stomach and known as *rennin*. This enzyme is especially abundant in the

mucous lining of the stomach of young mammals and is extracted to be used in the manufacture of cheese.

The fifth edition of Harper's *Review of Physiological Chemistry* (p. 177, 1955) says of rennin: "This enzyme causes coagulation of milk, and is important in the digestive processes of infants because it prevents the rapid passage of milk from the stomach. In the presence of calcium rennin changes irreversibly the casein of milk to a paracasein which is then acted upon by pepsin. This enzyme is said to be absent from the stomach of adults."

Although, heretofore, it has been thought that the sole function of rennin is to coagulate milk, it seems from Harper's statement that it may be a true digestive enzyme. It changes casein to paracasein so that pepsin can act upon it. Enzymes are specific in their action. Each enzyme acts upon a particular type of food and certain of these can act upon a starch or a protein only after other enzymes have first acted upon them and changed them from their original composition. Harper's statement seems to imply that pepsin acts upon paracasein rather than upon casein.

If this is the true relation of pepsin to the digestion of casein it means that rennin is essential to the efficient digestion of this protein. Rennin becomes of far greater importance in the digestion of milk than has heretofore been thought.

Rennin has been the subject of much controversy among physiologists. There was, first, the question: does rennin exist or does pepsin do the work ascribed to this enzyme? French and German investigators finally succeeded in establishing, to the satisfaction of everyone concerned, the existence of rennin as separate from pepsin. This did not end the controversy. While investigators now admit that rennin does, indeed, exist, many of them assert that it never exists in the human stomach, contending that it is found only in the fourth stomach of the calf.

In his *Advances in Enzymology* (London, 1954) Berridge defends the view that rennin is never found in the human stomach. He says that "Experiment tends to confirm the absence of rennin from human gastric juice." On the other hand, Eusterman and Balfour, in *The Stomach and the Duodenum* (1936) state that, "according to a number of investigators, rennin tends to disappear from the adult stomach." This statement implies that somebody, somewhere, found rennin in the human stomach, while its disappearance from the adult stomach has led to the suggestion that Berridge, who makes no distinction between infants and adults, made all of his experiments on adults.

In the second edition of his *Textbook of Medical Physiology* "1961" Arthur C. Guyton, M.D., says "rennin is found in the gastric juice of babies in large quantities, but it is present only to a very slight extent if at all in the gastric juice of adults. Also casein seems to be digested by babies much more easily than it is by adults, presumably because of rennin activity in the baby's stomach."

In the 1950 edition of *The Physiological Basis of Medical Practice*, Best and Taylor say that the rennin content of adults is "low" and provide us with the following data: "Rennin is especially abundant in the gastric mucosa of young animals, while pepsin is present in minimal amounts...The optimum pH for the action of rennin is between 5 and 6.5, and it is quite inactive at the pH of the gastric contents of the normal adult. In the infant, however, the pH of the gastric contents (5-6.5) is around the optimum for the action of this enzyme.

This indicates that the digestive processes required for the digestion of milk are somewhat different from those required for other foods and especially for other proteins. It is essential that the milk be coagulated and that the casein be converted into paracasein. I have seen two patients on a milk diet in which the milk did not coagulate, but was rushed along the digestive track into the colon and expelled in an unchanged fluid state. A glass of milk would be taken and in less than five minutes it would pass from the colon. Perhaps, in the absence of coagulation, milk would never be digested, but would pass through the digestive track too rapidly for the digestive enzymes to do their work.

In large numbers of other cases I have seen very large stools pass that were composed of large, hard milk curds that were white, apparently having undergone no digestion. Coagulation alone is not sufficient to

assure the digestion of milk. In a few of these cases, the curds have been so large and there have been so many of them that bowel impaction resulted. We frequently see white curds in the stools of infants, indicating that, although the milk coagulated, apparently in a normal manner, the curds were not digested. We assume in these cases that milk has been taken in excess of enzymic capacity.

As rennin is active in low acid medium and is inactivated by the normal gastric juice of the adult, and as it is concerned solely with the digestion of milk, it should come as no surprise to us to learn that it is not secreted by the adult stomach. In this connection it should be stressed that the acidity of the juice poured into the stomach is determined by the food eaten. Milk taken alone will occasion the flow of gastric juice that is low in acidity. Even in early childhood, when there is still a supply of rennin in the stomach, taking flesh, eggs or other protein at the same meal with milk will tend to result in the secretion of a highly acid gastric juice that will destroy or inactivate the rennin and interfere with or retard milk digestion, hence the wisdom of our rule: *take milk alone or let it alone*.

Rennin is apparently involved exclusively in the digestion of milk and tends to disappear from the gastric juice (is no longer secreted by the stomach) when the normal time to wean the child approaches. Some physiologists say that the concentration of rennin in the adult gastric juice is low; others say it isn't detectable. A two year old baby normally has a mouth full of teeth and can begin eating solid foods. At this age, also, the salivary glands begin the secretion of the enzyme ptyalin, which is necessary to starch digestion! Intestinal enzymes essential to starch digestion begin to be secreted at this time, also.

Thus, both the presence of adequate chewing apparatus and the secretion of digestive enzymes indicate that now is the time to begin the feeding of solid foods. In an article by a dentist, which appeared a few years ago, the author makes the statement that the baby should be weaned when the first two teeth are cut, as this signifies that solid foods are now to be taken. Of all persons a dentist should know that two teeth do not enable a baby to chew foods adequately. As these first two teeth are in the front (are biters and not chewers), the baby is certainly not physiologically or anatomically equipped for such chewing.

When the first teeth are through and the starch-splitting enzymes are being secreted, there starts a decline in the production of rennin; this is to say, its secretion begins to decline at the age of two. It continues to be secreted in decreasing amounts during the next three to four years, that is, during what I have called the *transition period* (see *Hygienic Care of Children*), in which the child is normally making the transition from the exclusive milk diet of infancy to the solid food diet of later life. During this *transition period* milk is normally taken. Should it surprise us to learn that when the child reaches the age at which it should normally be fully weaned its digestive glands cease to secrete the enzymes that are specially related to milk digestion?

One question comes to mind that I can find no data for an answer. It is this: Does the individual who continues to take milk regularly, from infancy into adulthood, continue to secrete rennin for a longer period of time than does the individual who is weaned at the normal weaning time of three to five years? This is to ask: Does the stomach continue to secrete rennin for an abnormally long period of time if the infant diet is persisted into late childhood and thereafter? Does the persistence of the need for rennin cause the body to continue to secrete it? If it does continue to secrete this digestive enzyme longer than normal, at what time of life does it disappear from the digestive juice of the stomach? If it continues to secrete rennin but in much decreased amounts, in those who continue to take milk, does this account for the fact that some physiologists find no trace of rennin in the subjects they use in their tests?

While the answer to this question (I have cut it up into several subordinate questions) may prove to be of no great practical value, it would prove interesting as well as instructive concerning the power of the body to adjust itself to varying circumstances of life, especially its power of the body to adapt its digestive juices and enzymes to the food eaten. Every such advance in knowledge of the chemistry of digestion provides us with added data to assist us in determining, not only the normal diet of man, but, also, and of equal importance, the normal mode of feeding.

Today's *nutritionists* wholly neglect all natural indications of the normal feeding of man. One food is as good as another and any food is equally as good at any time of life as at another, providing the

commercial manipulators of our foodstuffs can prepare it in a manner that it is acceptable to all ages. For example, although we know that during the first period of life after birth, even the lion cub does not eat flesh, our *nutritionists* do not hesitate to advocate flesh food for the human infant at a period of its development when the young carnivores of all kinds are still drawing their nutriment from the maternal font. Arrogance and egotism cause them to assume that they can improve the normal order of feeding. The results of their efforts are not encouraging.

While considerable confusion exists about rennin, there is one thing about which there is general agreement: namely, *the adult human stomach has no rennin*. Berg and others have shown that the adult organism does not use milk as efficiently as the rapidly growing organism and that, milk is base-forming in the infant and acid-forming in the adult. Berg attributed this to the more rapidly growing organism. May it not be, in light of the foregoing that the greater efficiency of the young animal in assimilating milk rests upon the fact that the infant and young child digest milk better? This suggestion derives support from the fact noted by Berg and others, that, adult organisms handle *sour* milk more efficiently, the characteristics of the milk having been greatly altered by the ferment action of bacteria.

Every indication of nature is contrary to the present dogma of the dairy industry and the medical profession that we must take our quart of milk every day so long as we live; that, even at the age of a hundred, we are not to be weaned. *Nature indicates that we are to be weaned at an early age*. In medical circles the tendency of the pendulum, just at present, is to swing violently and far in the opposite direction. In increasing numbers, medical men are blaming milk for a growing number of illnesses in children and adults. From being the all-good milk is rapidly becoming the all-bad. Certainly the assumption that invalids and convalescents, who have weak digestive powers, should be fed milk like an infant, because in their enfeebled condition they can handle milk better than other foods, is no longer tenable.

The *Hygienist* will see in all these facts a justification of Graham's condemnation of the use of milk and milk products by the adult and his observation that the use of milk by the adult makes him logy and lazy. Trall also pointed out that milk is not a normal part of the adult diet. Those of us who have had an extensive experience with the milk diet, formerly so strenuously advocated as a near-panacea, will discover in the foregoing facts at least partial explanation of the many troubles that the milk diet produced. Polyuria, constipation, diarrhea, bowel impaction, nausea, much gas and discomfort, increased blood pressure, a water-logged state of the tissues (edema), catarrh, indigestion and other troubles arising out of "the harmless practice of overfeeding on milk," necessitated all manners of manipulations to make it acceptable to patients.

*From Dr. Shelton 's Hygienic Review, pages 274-276, Aug. 1969.*

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > Article #3: Well, You Wanted To Know! by V.V. Vetrano, B.S., D.C.

### **Article #3: Well, You Wanted To Know! by V.V. Vetrano, B.S., D.C.**

**I have noticed that honey is stimulating. After giving just a teaspoon to my baby, I noticed that she would not sleep the rest of the day.**

Your observations were correct. Honey is a stimulant. The excess of pure sugar and the formic acid it contains give honey its stimulating qualities.

It is often used by athletes exactly for this purpose, although it is thought of as "quick energy," because the stimulating effect is not often understood.

Actually most people overeat for stimulating purposes, although they don't realize it. Any eating which is done in the absence of genuine hunger causes bodily activity which is not compensated for by an addition of nutriment, as most of it decomposes and poisons the body. There is a net energy loss which results in enervation.

### **Could you explain the value of honey mixed with lemon juice when fasting?**

Those who fast with honey, lemon and water are not fasting. They are on a restricted diet and not a good one. If they abstain from all food except minute quantities of honey, lemon and water, thus lightening the burden of digestion, undoubtedly the body will benefit from the absence of heavy and indigestible foods. Most of the time the honey is taken in huge quantities, and these types of "fasts" are decidedly harmful. The persons on this diet are enabled to continue working, and therefore secure no rest. Very few benefits, if any, are the outcome.

The closer one comes to a genuine fast, with water only, the greater the results. Beneficial results are more frequent and more quickly achieved when truly fasting. There are no means known as excellent as the genuine fast for recovery of health.

One may hate the thought of fasting completely and try all sorts of trick diets or juice diets rather than enjoying a real fast. People lose a lot of weight with these eliminating diets, wasting their reserves, and actually putting themselves into conditions where they are unable to fast. Consequently, it may take them years to recover, whereas if they had not played around and if they had fasted immediately, they would have recovered in a short time.

### **Why is raw honey not good for you?**

Honey has about the same composition of minerals as white sugar. It is almost as devitalizing as is white sugar. This is why the honey bee can live on white sugar but not on brown sugar. Brown sugar has more minerals and will clog up the delicate digestive system of the bee. Honey does not combine well with any food. If taken with fruits, which do not need it, it will cause fermentation. If taken with cereals, it does the same thing. Honey also causes decomposition of protein foods and ferments itself from having been held in the stomach as long as necessary for the completion of protein digestion. Honey also contains a preservative besides being an animal product. The bees add some of their own secretions to their honey, and in the process, they add a preservative which is toxic to man. Honey is an evaporated product and as such is not as nutritious as foods which have not been evaporated. Evaporated foods lose many minerals and vitamins during evaporation because these come in contact with the oxygen of the air and are rendered inorganic and non-usable to man. An occasional indulgence in honey will not be extremely detrimental to a person but to make a habit of eating honey daily will definitely rob the body of alkaline minerals and cause an excess of mucous.

Most people purchase light honeys and the mineral and vitamin content of these is extremely low. The darker honeys are more nutritious but less tasty. Another evil is that many honeys sold in the ordinary supermarket have been adulterated with corn syrup and white sugar. The clarifying process to make honey less cloudy removes up to 35 to 50 percent of the original vitamin content so the only "good" honey is the unclarified type sold in the hive. If you rely solely upon fresh fruits for your sugar, you are much better off.

## Article #4: I Choose Survival

*Viktoras Kulvinskas Own Case History From His Book "Survival Into The 21st Century" Pages 231, 234 and 235*

While in college, I pushed myself to experience as much as possible. Born under the Piscean sky, of delicate constitution, this often proved disastrous. My living and eating habits were deadly.

By 1965, I knew all the nurses and doctors at the infirmary. They were very generous with tranquilizers, sleeping pills and pain relievers. These I added to fifteen cups of coffee and two packs of cigarettes per day, plenty of alcohol, chronic over-eating (by age 26 I was a chubby 190 pounds). In spite of many ailments, I always felt that one day I would be healthy.

A frightening experience shook me from this complacency. I was running up the stairs to a class on the fourth floor. Pain constricted my chest, but I made it to the office, poured a cup of black coffee and started to lecture.

My hands were shaking, perspiration poured from my face and armpits. I could not focus my thoughts. The pain in my heart was sharp. I did not think I would leave the room alive. By sheer force of will I managed to, finish the lecture.

Suddenly I knew what I must do without delay. I purchased some mild tea, fruits and vegetables. Then I drove to my log cabin, stopping to see my landlord. I told him that I was not well; that if I needed help, he would hear a continuous blast from a car horn which I would rig so it could be triggered from my bed. In that event, he should do whatever he thought necessary for me.

Walking up the two hundred foot incline to my cabin, I had to rest several times because of the sharp pain in my chest. My legs felt like lead. My varicose veins were screaming as if ready to burst.

I went to bed, but could not sleep. Since I was giving up coffee, cigarettes, alcohol, meat, milk and sleeping pills; I vaguely anticipated withdrawal symptoms. I lay clutching the car horn alarm for long distance companionship.

By 3 A.M., my nerves were on edge. I felt paralyzed inside my exhausted body. Headache, cramps and sweat came in waves. The palpitation of my heart increased. It started racing. I clocked it fearfully at 1:30, at which point I passed out.

I woke at 7 A.M., surprised and happy to be alive. I felt well enough to go back to school, but this was illusory; soon I felt exhausted. I went for a five-minute walk. All day, I wondered, what will the night be like? Will I survive it? Outside of knowing that drug withdrawal usually takes about three days, I had no knowledge of fasting, nor had I known anyone who had fasted.

For four days I experienced only minor discomfort, but the nights were sheer torture. However, as the days progressed, I began to feel more certain about my future. I increased the length of my daily walks and by the fifth day fell asleep at 11 p.m. from tiredness. By the seventh day I was running a few minutes and preparing the soil in the garden. I prayed, thankful to be alive to experience the simple delights of living.

*During ensuing experimentation with diet, I discovered that my favorite food, milk (supposedly the perfect food) is a major source of colds and a factor in most respiratory disorders.*

*Pasteurized milk had been the staple in my diet in early childhood. For the first years of my life, doctors predicted my death as a matter of course. The milk diet (I know now) contributed to disorders of the respiratory and lymph system: tonsillitis, flu, pneumonia, diphtheria, colds, measles, mumps, bronchitis. On several occasions, I developed a high fever accompanied by large, running sores and boils (my body's attempt to cleanse itself). For two months I was semiconscious during a bout of typhoid fever.*

Family love and strong will to live enabled me to survive.

Doctors continued to predict that I would never be healthy. They said my heart was permanently damaged by a triple dose of diphtheria toxoid given me by mistake. It would have killed a normal child, they said.

*The poverty in post-war Germany made it difficult to obtain eggs, milk and meat. I spent much time barefoot in the woods gathering berries, mushrooms, nuts and wild fruit to contribute to our largely vegetarian diet. These simple foods restored my health.*

During this detoxification period I had frequent colds and difficulty in eating. Once, within a 24 hour period, I developed a fever of 106 deg. F.; my skin became covered with sores. Because I fasted on liquids and rested, the condition disappeared within 3 days. *Much of the past dairy-induced mucus was eliminated though the skin in the form of boils which grew into the size of plums taking about 3 to 4 weeks, followed by opening and discharge of pus.* Within a period of a year I had 5 such events. This finished my basic body cleansing process.

Arriving in America at the age of ten, I embraced its luxuries: ice cream, milk, soda, white bread, hot dogs, candy, canned foods and processed bakery products. Within a year my skin became pimply, and I visited the dentist for the first time and developed severe colds. By the age of 16, I had varicose veins. At 19 I had a duodenal ulcer and tumors on my hand. I suffered migraine headache at least once a week. One of the outstanding characteristics of my diet was an excessive use of dairy products in the form of milk (up to three quarts a day), ice cream (on occasion I have eaten half a gallon), condensed milk, swiss cheese. I constantly spit sticky mucus.

Even after the healing crisis in my cabin, I continued this habit. Indigestion was sometimes so bad that I had to substitute lemonade for milk. In a few days my digestion would improve; then the desire to return to milk would become so strong I would repeat the pattern.

In the morning, after a few yoga postures, I would eat a breakfast of milk and cereal. Within minutes the great sense of well-being would vanish, replaced by a fuzzy head, runny nose and long congestion. Initially I supposed that I had not felt so well as I had thought. However, constant repetition convinced me that the culprit was *milk*.

I decided to resolve the problem. After three days of lemonade, I tried, on successive days, milk, yogurt, cottage cheese, dried milk, condensed milk. Every one of them induced the same reaction.

Though I was working very hard at this time as a computer programmer, my body was sick. I suffered from insomnia, migraine, stomach ulcer, varicose veins, indigestion.

It seemed time to retire (very appropriately, for at the age of 29 I showed all the signs of old age—my hair was graying and I was losing it quite rapidly).

The books of Ehret and Drs. Walker and Warmbrand gave me hope. I wrote to the authors and met some of them personally. Dr. Warmbrand put me on a vegetarian diet and made chiropractic adjustments. Immediately my digestion improved.

One doctor introduced me to Ann Wigmore. At the Mansion I became acquainted with grass juice and sprouts. The meal, served in famine proportions, looked wriggly; but it satisfied my appetite and agreed with my body. I read "Why Suffer." It opened visions of peace in the natural world and the power of the healing strength of grasses. I moved into the Mansion about one month later in May, 1968.

During the early stages of transition into vegetarianism, I had periodic bouts of cleansing reaction. Sweating was so profuse that I had to change my socks four times a day. On two occasions open sores discharged toxins stored for years. At times very irritable, I, found the best solution to be silence. Cramps were relieved by massage. Pain and headache responded to zone therapy.

With a cleansing diet my weight dropped, in a period of six months, from 160 to ninety-five pounds. As my body started rebuilding I gained weight and now weigh 135 pounds.

Over the years, I have learned much about health and the needs of the body, but, like many busy people, I have neglected to pay enough attention to my bodily requirements.

One of the most important ingredients of health is adequate rest, which I have never obtained. Under city conditions, sunshine and pure air are not available. There never seems enough time for yoga, fasting, relaxation or meditation. My body has regenerated a good deal on the live food diet, in spite of these handicaps.

Now I have reached a time in life when the longing to be in the countryside is strong. Survival in the city is impossible. Next year, if the country is still intact, I plan to pursue the development of communities away from the city, in the north, the tropics and on islands, for surviving the crisis of this planet. We have little time left to prepare ourselves and our shelters.

However, survival into the 21st century is possible if we center our energies and apply the New Age teachings. This is the only task that has any meaning in our time.

### **Article #5: Excerpts from "Compassion: The Ultimate Ethic" by Victoria Moran**

"The new ways are solidly established. About 95% of egg-laying hens, virtually all...turkeys and half or more of beef cattle, dairy cows and pigs are maintained in some type of factory system."

Although factory farming has increased animal suffering tremendously and therefore adds fuel to the ethical vegetarian cause, it must be remembered that vegetarianism existed prior to mass-meat innovations, and its adherents eschew not just "farmed" flesh foods but also those obtained by hunting or fishing.

Up to this point, ethical vegetarians and vegans are of one mind. The difference comes in the vegan's seeing the entire animal-food and products network as a single entity:

"True, cowhide is only a byproduct of hamburger, but if cows were killed for their skins, would their flesh be any more morally edible so long as you did not wear leather?"

"And what about the veal floating invisibly inside every glass of milk...There can be no quart of milk where there is not cutlet of veal. If your lips are white with milk, it is because someone's else's are red with blood."

The vegan is acutely aware that when most people stop eating meat, they increase their egg and cheese consumption markedly, "which means that any relief of suffering for the animals exists more in hope than in fact." I am personally a prime example of this: it was after becoming a vegetarian, not as a meat-eater, that I could go into ecstasy over a cheddar omelet. I probably know every eatery in Chicago's western suburbs that serves fluffy omelets. I even devised a system for protecting myself from the flat variety: a restaurant with linen napkins is sure to make fluffy omelets; with paper napkins, you take your chances! In any case, I presumed, as do most of the city-bred, that the cheese for my omelet came indirectly from a creature endowed by Nature with extraordinary abilities for milk manufacturing. It never occurred to me that the cow, like any mammalian female, produces milk for her young and must therefore periodically give birth to keep in lactation.

I shared with other urbanites the naive notion that only "surplus" milk is taken, after calves have nursed; but today almost no dairy cow is permitted to suckle her calf more than THREE DAYS, if that long.

According to the 1965 report of the Brambell Committee, a British governmental commission which conducted extensive research into food-animal treatment in the British Isles, "Separating the calf from the mother shortly after birth undoubtedly inflicts anguish on both. Cattle are highly intelligent, and attachment between the call and the mother is particularly strong."

A calf may go almost immediately for slaughter as veal; and the rennet from the stomach of a newborn calf is used in the processing of most commercial cheeses, rendering the product unsuitable for even lacto-vegetarian use in the strictest sense. (Some companies do now produce rennet-less cheeses which are made with vegetable coagulants; they usually must be purchased at health food stores and are more expensive than the mass-marketed brands.)

Early slaughter may be considered a more fortunate fate than that of the calves who go to white-veal units, where their 14-week lives are spent confined in wooden crates or stalls 22 inches wide by 4-1/2 feet long.

They are fed a liquid diet deliberately deficient in iron and certain vitamins, to promote the desired (anemic) paleness of flesh. Lack of roughage induces them to nibble at their crates and hair; and no bedding is provided, lest they eat it. (In deference to non-vegetarians concerned about this situation, we may state that many have boycotted veal; vegans applaud their efforts as far as they go, but urge them to go further.)

A few males may be reared for breeding, and those females deemed suitable for raising for dairying are fed milk substitutes to encourage their precocious development so that at 18 to 24 months the continuous cycle of pregnancies may begin.

These animals also will, of course, eventually be destined for the slaughterer's; and it is curious to note that life in a beef herd is (comparatively speaking) usually much more enjoyable than that endured by dairy cows and their offspring. The calves of beef cattle are "allowed to suckle...and graze in the fields until the time comes for the fattening pens and the slaughterhouse, but the surplus calves from the DAIRY herds are often sent to market when a week old (or less) and bought for rearing in intensive beef units...encouraged to overeat and...kept closely confined so that the minimum proportion of the food is used up for their bodily functions."

The vegan does not see this state of affairs as inconsequential or even as simply "unfortunate but necessary in a less than perfect world." He regards egg production similarly. Probably no creature outside the vivisection laboratories is subject to a more pitiable life at the hands of modern man, than is the chicken. Those idyllic barnyard scenes with hens pecking outside a chicken coop and the rooster serving as a colorful alarm clock for anyone within earshot still exist in very limited number, but the eggs from those family farms don't put a dent in the number of eggs consumers demand. To meet this, severely intensive systems have been devised since cage laying and indoor confinement began their rapid spread.

Originally, one-bird per cage was the rule. When production increased slightly with two birds and no decline was noted with three, four were tried; and now five fully grown hens in a 20x24-inch cage is routine in a mid-sized hen battery like the one I visited near Yorkville, Illinois. The 300,000 leghorns of "White Hen Farms" produce an average of 100,000 dozen eggs each week for a supermarket chain. (1,200,000 eggs, or four per week per hen. -ed.)

The "house" I was allowed to tour is an older 2-deck system (that is, 2 cages high), although White Hen's more modern units are triple-tier, and some large batteries—boasting up to one million hens, sometimes packed as tightly as NINE to a standard cage—have hen tenements (henements?) 4 or 5 rows high.

White Hen manager Walt Schultz, a personable businessman, explained that "Higher densities are being researched—more layers per square foot of building...It's the only way to be competitive. We have to increase capacity to be more efficient." And efficient it is: that particular operation runs with 26 full-time and 18 part-time employees, only 8 of whom are actually involved in maintaining the (three hundred thousand) birds.

Chickens for such plants are obtained from primary breeders who cage-rear pullets to laying age. The males are spotted by "sexers" at hatching. "Usually they go into the discard box, where they are left to die. Sometimes they are returned to the incubator; the heavy door is closed, the fan is shut off, and they suffocate."

At twenty weeks, birds ready to lay are transported to the egg farm where they will spend nine months in production. Feed and water are mechanically conveyed in, and eggs and wastes are similarly carried out. "Stimulighting" from fluorescent bulbs overhead provides 17 hours of artificial daylight believed to stimulate laying.

Overcrowded conditions—with a squeeze of 4 hens into cages of 1 square foot, reported at the Hainsworth Farm in Mt. Morris, New York—mean that the birds can not spread their wings (even one at a time!) and can scarcely turn around. Wire flooring often injures their feet, and hens have even "grown fast to their cages."

Under such stresses, the instinctive social structure and "pecking order" cannot develop; the conditions instead lead to what the industry calls "vices," notably feather-pecking and cannibalism. The British found the aforementioned "stimulighting" to aggravate this, so there dimming of lights—"twilighting"—is preferred.

On both sides of the Atlantic, birds are de-beaked at one week and again at 3 to 5 months when the beak grows back. This, according to the zoologist, F.W. Rogers Brambell in the previously quoted Brambell Report, "deprives the bird of...its most versatile member...between the horn and the bone is a thin layer of highly sensitive soft tissue, resembling the 'quick' of the human nail. The hot knife used in debeaking cut's through this complex of horn; bone and sensitive tissue, causing severe pain."

Every instinct—walking about, scratching the earth, dust-bathing, nest-building, mating, being part of a flock, experiencing the outdoors—is thwarted, and it all ends with the slaughterhouse and the soup can. ("Broilers" are not as yet raised this intensively on a large scale because the resultant sores and abscesses would diminish their market value.) Ironically, there are laws in both the United States and Great Britain stating that caged birds and animals be given adequate space for basic functions; in both nations' statutes, however, the loophole exists excluding those kept for FOOD from "equal rights under the law." (In other words, it is for songbirds, pets, those creatures who may normally be expected to elicit some feeling of kindness and sentiment in their owners anyway; it specifically excludes the very ones most in need of succor and most likely to be mistreated for profit. - ed.)

If "free-range" eggs were widely available (and reliably identifiable) at realistic prices, would those who are currently vegan use them? Some might (although they would then no longer be vegans) but most would still avoid them for the reasons early vegans did. To eat a fertilized egg is in effect to consume a chicken before it is born ("The ethics are borderline," I was told); and unfertilized eggs, the products of a bird's sexual cycle, can hardly be regarded as natural food for man.

Furthermore, vegans choose not to rear food animals themselves, and do not ask others to do this for them. Besides, there then must arise the insoluble dilemma of lacto-ovo vegetarianism: Given the demise of the meat industry, who is going to support hens past their prime, cows who can no longer produce milk, or the male chicks and calves who are now routinely killed at an early age? This is the question that vegan thought puts squarely before the vegetarians who, understandably, do not care for the question.

## Article #6: What Happens To The Calf?

Few people realize that cows have to be subjected to yearly pregnancies so that the milk, cheese and cream that form a substantial part of the diet of the lacto-vegetarians and meat eaters may be produced. Many imagine that the cow is only relieved of her surplus milk after her calf has been satisfied, but hardly any cows in the dairy herds are allowed to suckle their calves for more than three days if at all. "Dairy calves are now nearly always reared by hand so that the milk which the cow provides can be sold." "Separating the calf from the mother shortly after birth undoubtedly inflicts anguish on both. Cattle are highly intelligent, and attachment between the calf and the mother is particularly strong." The calves, the inevitable byproduct of these continuous pregnancies, have five possible fates:—

1. They may go to the slaughter almost immediately—probably to provide the veal for veal and ham pies. The rennet used to make most commercial cheeses has to be taken from the stomach of a newly born calf.
2. They may be much more unfortunate for they may go to a white veal unit to spend the whole of their lives shut up in narrow Wooden crates. After the first few weeks they have no room even to turn around. They are fed on a special liquid diet designed to promote maximum growth in the minimum time and to keep their flesh "fashionably white." They are denied the roughage that their special digestive systems as ruminants require so they are often reduced to eating their own hair and nibbling their crates. They are given no bedding because their craving for solid food would make them eat it. The old practice of "bleeding" to whiten the flesh is now illegal but their iron take is kept to the minimum necessary for survival lest the meat should be tinged with red. Many emerge from their crates at the end of their fourteen weeks of existence suffering from stomach ulcers and abscesses, and with legs too shaky to support them as they are driven into the slaughter-house lorry. The Brambell Report says, "Calves at large are normally active and playful animals."
3. The home production of beef has gone up 50% since the war and "a recent survey has shown that 80% of the beef produced is a byproduct of the dairy industry." Calves from *beef* herds often have a comparatively tolerable fate, being allowed to suckle, run with their dams and graze in the fields until the time comes for the fattening pens and the slaughter-house, but the surplus calves from the *dairy* herds are often sent to market when a week old (or less) and bought for rearing in intensive beef units. "Friesian calves are ideal for extremely intensive systems." Fed for twelve weeks on a largely cereal diet, they are encouraged to overeat and are kept closely confined so that the minimum proportion of the food is used up for their bodily functions. "There is a danger of poisoning due to overeating."
4. In these days of artificial insemination few calves are reared as bulls. A calf selected for such a fate may be allowed to suckle for a period. He will be carefully reared to produce the physique of a good sire with maximum fertility. Not that his physical powers, superb though they may be, will have much significance in the life designed for him. From ten to twelve months of age he may serve cows weekly, spending the rest of his time in solitary confinement. More likely these days he will be required to serve canvas "cows" and rubber tubes. The Ministry of Agriculture pamphlet on the care of bulls advocates an exercising yard attached to his shed with walls of a type he can see through for "boredom can produce viciousness" an admission that animals have a mental and emotion life! Aged bulls are often castrated before they are shut up to fatten for the butcher.
5. If female the calves may be deemed suitable to rear as dairy cows. Dairy calves are removed as soon after birth as possible so that "the cow may settle down again in the herd," i.e. she is granted the minimum time to get over the strain of her frustrated pregnancy so that her milk as soon as possible can go to produce the all important profit. Fed on milk substitutes the calves

development is encouraged so that at eighteen to twenty-four months they can begin the cycle of continuous pregnancies. To quote from the "New Scientist," January 13th, 1972, "The modern dairy cow leads a hell of life. Each year she hopefully produces a calf which means that for nine months of the year she is pregnant. And for nine months of each year she is milked twice a day. For six months she is both pregnant and lactating."

Details of the ailments she can succumb to while meeting these demands make horrifying reading and so do the descriptions of the remedies used (see the various farming journals). Giving birth is often a prolonged and painful business for the cow to be rewarded only by separation from her baby. Cows often cry out and search for their calves for days after they are taken away. When after years of exploitation her milk yield drops then she is sent to the slaughter-house immediately. Worn out cow's meat is not popular in this country so they are commonly sent abroad for slaughter.

Comparatively lucky are the cows and calves that can live out their lives and suffer their butchering near to the place of their birth. For most there are long wearisome journeys, rough handling and standing in market places before being taken to slaughter-houses or new farms. The modern slaughter-houses are often miles from the farms on which the animals are reared, and it is not deemed "economic" to feed animals that are going to be slaughtered. The "humane" killers lessen the pain of the death blows but not the terror of the waiting and the violence of the handling that must precede their use.

And all this to produce food for humans that is not necessary! Human babies should have their mother's milk, and children and adults the solid food appropriate to their dentition and digestive systems. These can easily be selected from richly varied plant sources. For babies and children where necessary or desired, for invalids and those who still like to take milk, the Plantmilk Society, formed and served by men who were deeply moved by compassion for exploited animals, has promoted "Plamil" the milk of human kindness. Other nutritious plantmilks are also available. But the dairy industry is inseparable from the cruel exploitation and degradation of helpless, highly intelligent animals.

## **Article #7: 'No veal' campaign protests treatment of milk-fed calves by Michael J. Conlon**

*United Press International*

WASHINGTON—The Humane Society of the United States is trying to discourage Americans from eating milk-fed veal because, it says, the animals are cruelly treated.

In a nationwide "no veal this meal" campaign, the society charges that most vealer calves raised for slaughter are isolated in narrow stalls and fed liquid diets low in iron "so the flesh stays 'fashionably white.' "

The campaign features ads in The New York Times and New York magazine as well as business-type cards that are being distributed to consumers to leave in restaurants where milk-fed veal is served.

"Dear Restaurateur," reads the card. "I enjoyed my meal here, but did not choose a veal entree because I believe milk-fed veal is inhumanely raised. I would prefer it if you did not offer this veal on your menu."

The group says most white veal that winds up on the nation's dinner tables "comes from calves raised in total confinement. Isolated in narrow stalls for their whole lives. Unable to turn around. Denied roughage."

The society said that need not be the case.

Veal raised in Britain, it said, are "housed in group pens, provided straw bedding, permitted to feed at will and to ruminate. Whether American veal producers will decide to adopt this system is uncertain."

It said one major domestic veal producer, Provimi Inc., had announced it will begin testing the British system as an alternative.

The society said it is urging support for legislation introduced by Rep. Ron Mottl, D-Ohio. His bill would establish a Farm Animal Husbandry Committee "to investigate how all farm animals—including veal calves—are raised under conditions of intensive confinement."

It said this is the first piece of legislation introduced in Congress to address directly the welfare of farm animals.

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > Article #8: Milk Surplus Continues To Grow As Price Climbs Ever Higher By Dan Carmichael

## **Article #8: Milk Surplus Continues To Grow As Price Climbs Ever Higher By Dan Carmichael**

*United Press International*

Milk is the most political food in America, the product of an industry that enjoys legalized price fixing and a system financed by tax dollars to the tune of more than \$2 billion a year.

Dairy executives wince every time the facts are repeated. Demand for dairy products is declining dramatically, production is skyrocketing and it costs U.S. taxpayers \$250,000 each hour for their government to buy the surplus.

National milk supplies are 10 percent above demand and it costs \$5,319 more every hour to store the surplus—or more than \$127,000 a day.

The system has been called "a national scandal" by numerous critics, including President Reagan's budget director, David Stockman.

Even the critics, however, concede the odds are overwhelmingly against a major change. The dairy lobby has 1 heavy clout and last year alone contributed more than \$2 million to congressional campaigns.

At the core of the system is a national network of milk cooperatives. The largest co-op—Associated Milk Producers Inc. (AMPI) of San Antonio, Texas—got caught in the Watergate scandal and its bagman carried \$100,000 cash in an overnight case destined for Richard Nixon's illegal "dirty tricks" fund.

After AMPI made "campaign contributions" to Nixon, the president allowed milk price supports to rise by 37 cents per hundredweight, which gave the industry an additional \$105 million to \$500 million.

The system works extremely well—for everyone except consumers. It is difficult to reform because its complexity is beyond the economic understanding of many voters.

American taxpayers are buying about \$2 billion of dairy products this year that no one wants. But the government is committed by law under an entitlement program to buy the surplus—no matter how much is overproduced deliberately.

The figures are mind-boggling.

Current stocks of dairy products—cheese, butter and dry milk—would fill a train stretching from New York to Washington.

As of April 30, 1982, the Commodity Credit Corporation had 411.7 million pounds of butter in storage, 550.5 million pounds of cheese and 917.7 pounds of nonfat dry milk. The annual storage cost: \$46.6 million.

Governmental warehouses across the nation are overflowing. Nonfat dry milk fills 180 huge warehouses. Another 127 are full of butter and 171 are overflowing with cheese.

The figure for butter is lower than normal because the government recently sold 220 million pounds to New Zealand—a dairy nation—at bargain prices.

Surplus dairy supplies have been increasing since 1979, when government expenditures jumped from \$46 million to \$1 billion in 1980, to \$1.9 billion in 1981 and \$1.9 billion this fiscal year.

Some of the surplus is rotting. Some of it is being sold at major losses overseas—losses that taxpayers are financing. Some of it is being given away.

In December, President Reagan ordered 100 million pounds of cheese given away, cutting annual storage costs by more than \$16.8 million.

The government has discussed several other options to reduce the cheese surplus, including dumping it in the ocean or burying it.

Currently, the government is buying about 9 percent of the total U.S. dairy production. The total in 1981 for milk and ice cream was a record \$18.1 billion, 9 percent more than the record set in 1980.

An AMPI executive, Leland Anderson, said 10 percent of the nation's dairy farmers would go out of business if the price support system were abandoned.

"It'll cause a drastic drop in production to the point where we won't have adequate supplies," said Anderson, the assistant to the AMPI manager.

"We would have chaos in the industry," Anderson said. "Everybody would be trying to dump on the market to get sales and undercut everybody else. The product would become worthless.

"And the ultimate result is a certain number of people would go out of business," he said. "Are you going to put 10 percent of dairy farmers out of business and have them looking for jobs in the cities where there, are no jobs?"

Critics say this means taxpayers currently are supporting one out of 10 of America's dairymen.

Agriculture Secretary John Block is seeking congressional approval to give him flexibility to reduce government price supports to discourage even larger surpluses, but he has promised to make only a relatively small reduction.

Under current law, the support level is \$13.10 per 100 pounds of milk. Block wants legislation giving him authority to set the support level—as opposed to specific minimum support levels mandated by law. He said he likely would not have to reduce the level lower than \$12 per 100 pounds.

Time is short because the price support level is scheduled to increase again Oct. 1, despite the 9 percent overproduction.

Even before Block's recent announcement, the dairy industry was mobilizing to defeat the administration's plan which Block said would save taxpayers \$700 million the first year.

The surplus milk program, designed to stabilize dairy prices, is regarded as the most expensive byproduct of America's complex array of agricultural support programs.

The prices that milk processors must pay to farmers are set by federal milk marketing orders. Premiums

are charged for drinking-type milk, which studies have indicated adds 2 to 8 cents per gallon to the retail price. The marketing order system makes price fixing legal.

Since the processor must pay the higher price anyway, the system keeps reconstituted milk uncompetitive with fresh milk—which, according to *Consumer Reports*, "is exactly what the dairy industry wants."

To give consumers a lower-cost alternative to fresh milk, the Community Nutrition Institute petitioned the USDA in 1979 to hold a hearing on pricing reconstituted milk lower than fresh milk.

Estimates by the USDA itself showed consumers would save between \$186 million and \$339 million a year. But the USDA did not respond until April 1981 when it denied the petition, saying such a move would cause major changes in the dairy industry.

A source in the Office of Management and Budget says "The price support program raises the price of milk higher than it would be in a competitive market. It's not a good deal for consumers. Also, large government purchases further increase the (retail) price of milk substantially—to the tune of hundreds of million of dollars, if not billions."

The reason milk prices are a lightning rod for public criticism, AMPI's Anderson says, is because of milk's high profile as a staple.

"It's the most visible food in America," he said. "That's why it has become the most political food in America. Everybody is concerned about the price of milk because they buy it every week."

"It's easy to say dairy farmers are ripping off the public, the government shouldn't be in the program, we'd save billions of dollars if we didn't have this price support program, co-ops and federal orders are causing consumers to pay more, all of that," Anderson said.

"But when you really get right down to it, I think dollar for dollar, we've got a situation here that has produced a product that is good for consumers, that they want, that they expect to be available fresh."

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > Article #9: Natural Foods by Patrick Malone

## **Article #9: Natural Foods by Patrick Malone**

### **They Refer to them as 'Healthy,' But some are Actually Hazardous**

*Knight-Ridder Newspapers*

Some natural foods that are supposed to make you healthy could instead send you to the hospital, medical researchers are discovering.

Scientists browsing through health food stores across the country are finding a cornucopia of unsafe—even illegal—herbs, barks, roots, seeds and other substances plucked from nature.

"This idea of just going and eating plant extracts is very bad," says Dr. Joseph Davis, chief medical examiner of Dade County. "There is a whole host of problems."

New clinical reports of deaths and serious illness are forcing a second look at suddenly hip herbal teas, tonics and folk nostrums. Hospitals have reported health food victims from New York to Colorado.

Plants as common as alfalfa and as exotic as devil's claw root, as harmless as parsley and as dangerous as apricot kernels are sold in health food stores with no warnings about their potential side-effects.

Vomiting, diarrhea, muscular weakness, hallucinations, rashes, severe allergic reactions, high blood pressure and death—all have been linked in recent medical journal reports to medicinal herbs found on health food store shelves.

Based on her 15 years of researching herbal teas from South America to South Carolina, Dr. Julia Morton of the University of Miami is convinced that cancer of the esophagus can be caused by drinking too many beverages rich in mouth-puckering tannin.

That includes teas as unusual as bayberry and as common as Lipton, as well as dry red wine. The tannin-cancer link remains controversial.

Not so with some other products, whose dangers are as unimpeachable as their naturalness.

State and federal agencies charged with protecting the public from hazardous foods and drugs admit they can't keep them all off store shelves.

"There are lots and lots of things out there that shouldn't be there," says Joseph Perret, a consumer safety officer at the U.S. Food and Drug Administration (FDA).

### **Examples:**

**Apricot kernels** — Rich in Laetrile, apricot kernels are considered illegal by the FDA when sold in health food stores. The FDA has seized tons of the kernels, which have killed at least three Americans by cyanide poisoning.

**Mistletoe tea** — Reputed in ancient times to be a remedy for epilepsy, mistletoe contains a poison similar to cobra venom. Children have died from eating mistletoe berries. So have mice sipping mistletoe tea in a university laboratory. The FDA seized a shipment of mistletoe tea two years ago as unsafe.

**Pokeweed root** — Sold as a powder in health food stores, touted for a variety of medicinal uses pokeweed also has killed children. The poison it contains also can cause diminished breathing and an inflamed digestive tract.

**Sassafras bark and calamus** — Both banned by the FDA in foods, they are known to contain cancer-causing chemicals. They can be bought in health food stores or ordered by mail from one of the country's eight major herb wholesalers, such as Green Mountain Herbs of Boulder, Colorado.

Other health food items are legal because scientific research about their benefits or harms is scanty. Still others are safe if used properly, but food regulations forbid labeling that gives any food a medicinal ring.

Sometimes the distinction between a food and a drug is invisible. That has enabled a substance like apricot kernels to slip through the holes in the regulatory net.

It is true with other plant products as well. As long as something is sold with no advice on how it can help or harm medically, it is legally a food.

The irony for the fledgling herbal industry rests on this thin legalistic line between food and drug. The word "drug" itself comes from a German word meaning "to dry," as in drying plants.

"We're in a twilight zone," says Mark Blumenthal, head of Sweetheart Herbs of Austin, Texas, and president of the Herbal Trade Association. Blumenthal, a 32-year-old vegetarian, started with a partner selling ginseng root out of a car trunk five years ago and now runs a \$1 million annual business.

Reclassifying medicinal herbs as prescription drugs would ruin the herbal industry, insist suppliers such as Blumenthal. At last estimate of the Pharmaceutical Manufacturers Association, a new substance requires \$50 million and nine years to reach pharmacies as a drug.

In its own defense, the herbal industry will ask the FDA to set toxicity standards and organize a research program to gather scientific knowledge about medicinal plants forgotten since the rise of the modern drug industry.

Already, industry researchers have scoured thousands of chemical and botanical journals to cull what little is known about the hundreds of herbs now sold.

Soon the Herbal Trade Association will issue its first policy statement against one of its products, pokeweed root, advising that it not be taken internally.

[Home](#) > [Lesson 33 - Why We Should Not Eat Animal Products In Any Form](#) > Article #10: Plant Products And Effects by Patrick Malone

## **Article #10: Plant Products And Effects by Patrick Malone**

*Knight-Ridder Newspapers*

Here is a list of some plant products sold in health food stores and their potential harmful effects:

### **Apricot kernels**

Contain amygdalin, otherwise known as Laetrile. Hydrogen cyanide is released when swallowed. Can cause severe headaches, vomiting, weakness, disorientation and death.

### **Pennyroyal oil**

Supposed to be used as a flea dip but often not labeled as such. Killed a young Colorado woman and caused sickness in two other women who took it trying to induce abortion. Center for Disease Control in Atlanta is investigating.

### **Juniper berries**

Irritate digestive tract.

### **Buckhorn bark, senna leaves, yellow dock root, jalap root, aloe leaves**

All powerful laxatives that can cause diarrhea.

### **Shave grass or horsetail**

Contains nicotine. In grazing animals has caused loss of appetite and muscular control, diarrhea, labored breathing, convulsions, coma and death.

### **Burdock root tea**

In one case, doctors reported a person drank half a cup and experienced blurred vision, dry mouth, inability to urinate and hallucinations. Other common plants with euphoric or hallucinogenic effects when smoked or drunk in tea include catnip, juniper, lobelia and wormwood. Lobelia can be fatal.

## **Camomile**

Can cause severe allergic reactions in persons allergic to ragweed, asters or chrysanthemums. Goldenrod, marigold and yarrow tea also should be avoided by people with such allergies.

## **St. John's wort**

Can produce a bad skin rash in conjunction with exposure to sunlight if drunk as a tea.

## **Sassafras**

It was banned by FDA in 1976 but now is considered possibly okay as a tea.

## **Devil's Claw Root**

Should be avoided in pregnancy; has properties similar to the hormone that induces labor.

## **Ginseng**

Can cause swollen and painful breasts, also high blood pressure with regular use of large amounts (several grams a day).

## **Tonka beans**

Contains coumarin, banned by FDA as food additive; sold in health food stores to fix scent of sachets and potpourris. Caused liver damage and growth retardations when fed to animals.

## **Snakeroot, mandrake root**

Sometimes sold as ginseng. Both considered poisonous. Mandrake root contains a hypnotic similar to belladonna. Snakeroot contains reserpine, which causes lowered blood pressure and "possibly severe depression.

## **Arnica or wolfsbane**

Can produce violent digestive inflammation, muscular weakness, collapse and death.

## **Blood root**

Causes vomiting; overdose can be fatal.

## **Mistletoe**

Berries are the most poisonous and have killed children. Leaves and stems used in tea also contain toxins that in large doses can cause muscle and blood vessels to contract, leading to shock and heart arrest.

In fairness says Rob McCaleb, lab director at Celestial Seasonings, several points need to be made in herbs behalf:

Practically any medicine is toxic in large enough doses. The same is true for medicinal herbs. Foods can be toxic too: Prune juice is a well-known laxative, though not labeled as such, and it can produce diarrhea just like drinking senna leaf tea.

But Celestial Seasonings is cautious. The largest herbal tea company with \$10 million annual trade, it

sells no teas with banned or suspected substances.

The problem, as the industry sees it, is educating the public in sensible use of herbs, most of which are harmless and inexpensive.

The education process will take years. The first problem is that many of the books and pamphlets sold in health food stores contain only erratic information about potential harms alongside lengthy statements extolling unproven claims of medicinal benefit. Very few books even contain *specific* instructions on how one would use the plant, i.e., the part(s) of the plant to use, how to prepare the plant, how much or how often one would use it, etc. One does not get the complete story when using just one source (or even several) for information. A book might list a number of herbs as being "good for the heart," but if these herbs were researched more extensively, one would find that some are so potent that they actually affect the heart's *rhythm*. Most books don't go into such detail, but obviously, casual or misguided use of such herbs is *dangerous*.

Health food store operators are often little help. Most, like Peggy Childers, district manager for the National Health Food Central chain in Miami, are careful to say: "We do not prescribe in any way, shape or form."

The potential danger of some plant extracts currently sold in health food stores is in dispute.

Ginseng is the best example. One of the hottest sellers in health food stores, it is reputed as an aphrodisiac and a general health tonic and stimulant.

Doctors use it in China to regulate blood pressure and blood sugar, but its only accepted medical use in the United States is in skin ointments. An estimated 5 million to 6 million Americans take ginseng regularly.

A new study by Dr. Ronald Siegel of UCLA found that long-term heavy ginseng users suffered frequently from nervousness, sleeplessness and, most significantly, high blood pressure.

The herbal industry believes those problems were caused more by the caffeine in beverages consumed along with the ginseng.

But no one can say for certain, and even an herbalist such as McCaleb says that studies of the benefits of ginseng have found, in most charitable phrasing, that it has "enhanced placebo effect."

Two other popular herbal items sold in health food stores are camomile tea and alfalfa tea. The herbal industry believes both to be completely safe.

But camomile can produce severe allergic reaction to those allergic to ragweed, and alfalfa has caused problems with barnyard animals: bloating in cattle, retarded growth in chicks, decreased egg production by hens.

*The Medical Letter*, a newsletter that evaluates drugs for physicians, published in its April 6 issue the most comprehensive listing to date of the dangers of plant products sold in health food stores.

Dr. Walter Lewis of Washington University in St. Louis, a contributor to the article, is bothered by public ignorance of the hazard and upset by the FDA's lack of action.

"They're just absolute idiots," he says of the FDA.

African tribes who use a substance like devil's claw root, reputed to induce labor in pregnant women, control its use better than the U.S. government, which allows its unrestricted sale, he says.

Licorice root in small doses makes a tasty flavoring but in large amounts can cause heart failure. An ulcer drug derived from the root is available by prescription in Europe but not in the United States because of its side-effects.

"The irony," says Lewis, "is that you and I can walk into a health food store and get all we want, completely uncontrolled, and a physician can't dispense it."

Tannin, a substance found in wine and tea, can soothe a sore throat. But the University of Miami's Julia Morton found an atypical incidence of cancer of the esophagus in Curacao, coastal South Carolina and other areas whose inhabitants consumed large amounts of beverages high in tannin. The British put milk in their tea because it neutralizes tannin.

Tannin has produced cancer in animals when injected, but no studies have been completed on its effect when drunk by laboratory animals. The National Cancer Institute does not classify it officially as a carcinogen and has no lab tests scheduled.

Morton believes tannin is no danger if consumed prudently. Still, she has stopped drinking tea in the last few months. Her favorite beverage is water.

### 1. Introduction

We live on a planet whose surface is mostly water. About 70% of the earth's area consists of oceans, lakes, rivers and other bodies of water. Your body is also mostly water. In fact, the human body is about 70% water. If you're an average person, you have about 45 quarts of water or fluid in you at all times.

The water in your body is responsible for and is involved with nearly every life process. Digestion, absorption, circulation, and excretion—water is the primary transporter of nutrients throughout the body and is necessary for all the building functions. Water also helps maintain your body temperature and is essential for carrying wastes from the body.

You'll lose about three quarts of water, on the average, each day in the form of perspiration, excretion, etc. If you live in a very hot or dry climate, you might lose as much as 10 quarts per day. This water must, of course, be replaced. Generally, three or four days is the longest person can go without replacing these fluids before serious damage and eventually death occurs.

Unfortunately, modern man replaces these lost fluids in ways that may be harmful to him. Alcohol, caffeine beverages, soft drinks, hot and cold drinks, drinking with meals—all of these beverages and drinking practices contribute to poor health.

The purpose of this lesson is to inform the reader about the harmful beverages that are used, the harmful drinking practices that occur, and the correct way of obtaining fluids for the body.

#### 1.1 The Harmfulness of Common Beverages

Water is the only fluid that can be used by the body. It doesn't require coffee, tea, milk, beer or soda pop for its functions. Everything that is drunk by man *that is not pure water* must either be classified as a food or as a poison.

If a drink is classified as a food (such as milk, fruit or vegetable juices, etc.) then it should be taken as a food, by self, and not drunk in addition to other foods. If a drink is a poison (such as alcohol, coffee, cocoa, soft drinks, etc), then you should ask yourself if you should drink it at all!

According to Dr. Herbert M. Shelton, water is the only true drink, and in his words: "The time to drink is when one is thirsty and when this time arrives, there is nothing to equal a glass of pure, clear, sparkling, cool water."

Beverages and drinks are now used as forms of entertainment. They are consumed out of habit or for the 'kick' they provide in the form of alcohol, caffeine, or sugar.

Almost everyone drinks excessively, and there are several reasons for this. Many of the common beverages do not satisfy thirst; indeed, many of them with the sugar and chemical content induce more thirst. Alcohol actually dehydrates the body. People drink with meals; they drink when bored, and they also drink because they eat a diet that is deficient in natural fluids.

The most harmful beverages such as coffee, tea, cola drinks, and alcohol are discussed first. Then the beverages that are used as food substitutes (juices, herb teas, milk, etc.) are also evaluated for their suitability in the diet.

[Home](#) > [Lesson 34 - The Harmfulness Of Beverages In The Diet](#) > 2. Harmfulness Of Common Beverages

## **2. Harmfulness Of Common Beverages**

### **2.1 Coffee, Tea, and Caffeine**

Perhaps the two most popular beverages in America are coffee and tea. Less than 9% of the population drink neither coffee or tea. About half the people in the United States have two to three cups a day of these beverages, and another one-quarter of the population drinks 6 to 7 or more cups of coffee and tea every day.

These figures mean that over 200 billion doses of the drug caffeine are consumed by people in this country every year. Most people do not think that their morning cup of coffee or glass of tea at lunch is a drug. Yet caffeine is addictive, causes withdrawal symptoms when discontinued, and induces both psychological and physical dependence. It sure sounds like a drug, doesn't it?

### **2.2 How Caffeine Affects You**

Caffeine is a stimulant of the central nervous system, similar to cocaine and amphetamines in this manner. It increases the heart rate and rhythm, changes the blood vessel diameter, and affects coronary circulation, blood pressure, urination, and other physiological functions.

As little as three cups of coffee have enough caffeine to increase the basal metabolic rate of the body as much as 25%. In other words, you are "speeded up" about one-fourth above your normal activity.

In 1973, a study on heart patients revealed that people who drank five or more cups of coffee daily had twice as many heart attacks as nondrinkers. Caffeine is now also a suspected factor in birth defects, diabetes, kidney failure, gastric ulcers, and cancer of the pancreas.

In large enough amounts, caffeine can kill you. The fatal dose of this drug is what is contained in about 70 cups of coffee. That may sound like a large amount of coffee, but it is not unusual for some coffee drinkers to consume about one-third that amount every day. About seven cups of coffee can produce acute toxic effects in individuals. Symptoms of caffeine poisoning include mild delirium, ringing in the ears, flashes of light in the field of vision, and trembling of the muscles.

"I'm mad at the world until I get my first cup of coffee," is a statement heard more than once. Why? Because the habitual user of coffee becomes so addicted to his morning drug that unpleasant withdrawal symptoms occur even overnight.

Dr. J. Murdoch Ritchie, a drug researcher, states that caffeine is physically addictive and withdrawal symptoms are quite common. "Indulgence in caffeine-containing beverages leads to a condition of chronic poisoning, resulting in restlessness, disturbed sleep, cardiac irregularities, and tachycardia (rapid heart rate). The essential oils of coffee cause gastrointestinal irritation and diarrhea is a common symptom. The high tannin content of tea (another caffeine beverage), on the other hand, is apt to cause constipation." The caffeine-beverages are both harmful and addictive.

Caffeine withdrawal can occur from just missing the "morning cup of coffee." Symptoms of caffeine withdrawal are headaches, irritability, inability to work effectively, nervousness, restlessness and lethargy. When a regular user of caffeine drinks ends their use totally, he may experience tight headaches in the back of the neck area and be quick to anger or irritation. These symptoms usually pass in around three days or less as the body detoxifies from its habitual caffeine load.

Although coffee is mentioned as the most widely known caffeine beverage, tea also has a large amount of this drug. Usually tea has about half as much caffeine as a similar amount of coffee (unless strongly brewed), but since many people usually drank a larger amount of tea than coffee at one sitting, they still receive a large dose of the drug.

Interestingly enough, many parents instinctively realize that coffee and tea contain a strong drug, and so they deny it to their children for a few years. I remember at how "adult" I felt when I was allowed to have my first cup of coffee at fourteen years old. Young children instead are often given hot chocolate or cocoa in place of coffee. *Yet cocoa and chocolate drinks have significant amounts of the caffeine drug as well.*

Not only that, but the cola soft drinks contain large amounts of the drug—sometimes as much or more than that in a cup of coffee. Soft drinks, however, have more dangers than caffeine associated with them, and that is the next topic.

### **2.3 Soft Drinks Are Hard Drugs**

In the news was an account of a young boy who drank 64 bottles of a soda drink, one right after the other, to win a two dollar bet. A young girl was given a case of soft drinks as a prize for her scholarship. She drank the entire case that same day.

Over 250 soft drinks are consumed each year for every man, woman, and child in this country. Many people drink one or two such drinks a day as a regular habit. It is not uncommon to find people who drink over 100 ounces of cola, pop, or sodas every day of their lives.

Some drink it the first thing in the morning. Others have it as the last thing at night. Still others have it with every meal or all through the day.

Soft drinks are addictive. They are a drug. They do damage to the body. They furnish no nutrition. They are a menace to your health, and the only thing "soft" about them is how soft they can make your teeth by dissolving them.

Cola drinks were discovered in 1949 to contain a solution strong enough to dissolve iron. As for human teeth, Dr. Clive McCay of Cornell University showed that soft drinks can completely erode tooth enamel and make the teeth soft as mush within two days.

The bad ingredient in this case is phosphoric acid—an acid so strong that it can erode granite rock, and yet it is a common substance in all soft drinks.

Besides phosphoric acid, soft drinks also contain white sugar (usually an ounce or more per drink), artificial flavoring and coloring, carbon dioxide, and caffeine.

The carbonation, or carbonic acid, in the drink (which makes it "fizz") was discovered by Dr. Hunter H. Turner to be a strong factor in the increasing number of nearsighted children and adults. Not only is the stuff bad for your teeth, but it destroys the vision as well.

There is so much sugar in a soft drink that heavy drinkers often get an extra *pound* of white sugar in their diet each day. Blood sugar levels shoot up and sink when soft drinks are consumed. The appetite is dulled, and valuable nutrients are depleted in an attempt to metabolize the sugar in these drinks. When soft drinks are taken with food, the sugar leads to fermentation instead of good digestion.

The coloring used in the drinks are usually coal tar derivatives. Almost every coal tar derivative that has undergone extensive testing has been labeled a carcinogenic, or cancer-causing, agent.

The caffeine in soft drinks is so high that a child who drinks 4 bottles within an hour has received .13 grams of this drug—an amount even termed excessive and dangerous by the medical establishment. Dr. D.G. Steyn of South Africa has demonstrated that cold drinks which contain caffeine (such as soft drinks) are actually more harmful than hot or warm caffeine beverages.

In the last twenty years, soft drink manufacturers have developed, "sugarless" drinks. Of course these are artificially sweetened. The sweeteners used are chemical products which also have been implicated as cancer-causing. Such drinks are often used by people desiring to lose weight. Unfortunately, while cutting down on calories, they may be building a tumor at the same time.

Soft drinks are not "soft"—they are *hard* on you and your health.

## **2.4 One For The Road**

Of all the beverages with harmful effects, alcohol is probably the most widely known and frequently abused. Seven million people in this country have a serious drinking problem. Probably three to four times that amount use alcohol so much as to interfere with their normal lives.

Over 30,000 people a year are killed because of drunken drivers. Tens of millions of work hours are lost each year because of alcohol. We lose millions of dollars every year to alcohol and its related problems.

Alcohol is not a "safe" drug. It is an addictive drug. Out of every eight people who drink, one will become a life-long alcoholic. You cannot find such a high rate of addiction among any other drug users.

Yet alcohol is treated as a non-drug by the government. They issue licenses, collect taxes, and allow manufacturers to spend 300 million dollars a year to push the drug.

Alcohol destroys the liver, contributes to ulcers, enlarges the heart, and kills brain cells. It destroys both the body and the mind. Alcohol must be recognized as the killer it is and no longer treated as a social lubricant or "harmless" relaxant. It is a drug and has no place in a healthful lifestyle.

## **2.5 Herbal Potions and Drinks**

Witches used to have their special "brew." They would toss toads and roots and hair and blood and herbs into a big pot and make their special tea. Today, people leave out the toads and blood but they still use the herbs, and they call their potion "herb tea."

Most of the drugs and medicines used have originally come from herbs. Herbs are drugs. They are not foods. A tea made from these roots, bark and leaves somehow has achieved an unearned reputation of being healthy. Drugs are never health promoting. A tea made from drugs (herbs) cannot be health promoting.

People have been fooled. Health-seekers who would never touch a drop of coffee or an alcoholic drink put away cup after cup of this witch's brew because they think herb tea must be good for them since the ingredients are plants.

Since herbs and their dangers are covered in a future lesson, you only need know that herb teas are *not* such safe and healthy drinks. They may be a stimulant or a depressant or a carminative or whatever, but regardless *every herb is a drug and a poison* and a drink made from them can in no way be considered suitable for human consumption.

## 2.6 Fruit and Vegetable Juices

Fruit and vegetable juices are the finest liquids we can drink—provided that they are obtained directly from the food itself and not artificially extracted.

Extracted juices, like those in bottles, concentrates, or cans, have undergone oxidation, deterioration, and fragmentation. An extracted juice is an unnatural food.

We are meant to *eat* fruits and vegetables, not drink them. We have a thirst center and a hunger center in our brain. When we drink something that was meant to be eaten, we confuse this mechanism. Our hunger center may tell us that we want to eat one orange. If we pour down a glass of juice containing three or four oranges instead, we are not listening to the true needs of the body.

This is one of the dangers of drinking extracted juices. They are so concentrated that it is easy to overload the body with one nutrient or the other. At the same time, these juices have no fiber.

Frozen concentrates, bottled and canned juices, or any juice made more than twenty minutes ago cannot be good for the body.

If juices are actively desired, then they should be made fresh, consumed immediately, and used only in the same quantities that you would eat them. For instance, it is quite possible to "drink" twenty or more carrots in a couple glasses of carrot juice. We're not equipped to handle twenty carrots given to the body in such a short time. It would be better if two or three carrots were juiced and then sipped slowly.

Even the consumption of freshly made juices cannot be strongly recommended. If you're hungry, eat. If you're thirsty, drink, and when you drink, make it pure distilled water.

## 2.7 What Can You Drink?

It seems like that everything you drink is not good for you. You might wonder what you can drink. First, realize that most drinking is due to a water-deficient diet. If you do not eat the wrong foods, you'll probably want to drink very little. Often drinking is a social activity—much like eating. People like to offer drinks as a sign of hospitality.

If you experience true thirst, then your best choice for a drink is distilled water. Should you wish to offer someone something to drink or if you feel a desire for "liquid" nourishment, then *freshly* made juices may be sipped slowly in small quantities. These juices are actually foods and should be consumed as foods. No other foods should be taken with these fresh juices.

Other than these two liquids, it is difficult to recommend any other beverages. If you can break the habit of drinking with your meals and if you can eliminate the salt habit, then your drinking needs will be very slight and easily satisfied..

All of the drinking done by most people is pathological and results from a poor diet and unhealthy lifestyle.

Drinking merely replaces lost fluids in the body. Treat it as such and you will find that clear, cool water will satisfy you on all levels.

[Home](#) > [Lesson 34 - The Harmfulness Of Beverages In The Diet](#) > 3. Harmful Drinking Practices

## 3. Harmful Drinking Practices

Besides the harmfulness of certain beverages themselves, the way in which they are consumed is also

detrimental to health and well-being. Drinking with meals, drinking hot and cold beverages, and using drinks as substitutes for good nutrition are harmful drinking practices that should be avoided.

### 3.1 Drinking With Meals

Drinking while eating is such a common practice that restaurants don't ask *if* you'll have anything to drink but *what* you want to drink. If no beverage is ordered with the meal, then water is routinely supplied.

Drinking while eating is a harmful practice because the beverage dilutes the digestive juices of the stomach. Since fluids leave the stomach faster than solid food, beverages tend to carry out the digestive juices of the stomach and the stomach is left without sufficient juices to carry on its work.

Drinking with a meal also encourages poor chewing of the food since it is frequently washed down in a swallow of water or whatever. Normally food must be thoroughly mixed with saliva in the chewing process for it to be easily swallowed. Beverages replace the role of saliva in this respect, and permit the gulping of half-chewed food.

Beverages are usually incompatible with the food eaten as well. Fruit juices, for example, are often drunk with starchy foods (such as orange juice and toast). The acid in the fruit juices suspend the digestion of the starches and indigestion is guaranteed. Milk, another popular meal beverage, requires its own complex digestive environment since it is more properly a food than a drink. When drunk with sandwiches, breakfast or whatever, fermentation of the milk occurs in the stomach.

Beverages with the meal would never be used if people took the time to thoroughly chew their food. Washing food down and diluting the digestive juices with fluids always result in only partial digestion of the food.

If thirsty, beverages may be consumed twenty to thirty minutes *before* a meal. After a meal consisting of fruit, water can be taken within thirty minutes; after a starch meal, two hours should pass before drinking, following a protein or fat meal, a full four hours should elapse before fluids are taken. In general, if thirst occurs before these times, it indicates that salted, spiced or unsuitable foods were eaten at the meal and should be avoided in the future.

### 3.2 Hot and Cold Drinks: Injuring the Body

If you or someone you know likes to drink a hot cup of coffee or tea, try this simple experiment: take a tablespoon of the hot liquid, just as you would drink it, and pour it onto the bare stomach. Most likely, you'll experience intense pain and perhaps some blistering.

Ask yourself this question: if the hot liquid does this to the *outside* of my stomach, what must it be doing to the delicate and sensitive tissues on the *inside*!

Hot drinks destroy the sensitive nerve endings in the tongue. They numb the senses so that discrimination of taste is lost. They scar the esophagus and stomach lining. They disrupt body temperature and digestion. Any liquid above 104 degrees (Fahrenheit) should not be drunk.

Similarly, cold liquids also disturb digestion. In fact, an ice cold drink can completely halt the digestive process. The inside of your body is a delicate, well-controlled environment. Digestion proceeds at a proper pace when this environment is kept constant. Pouring a glass of ice water into the stomach is like taking cooking food from an oven and sticking it into a freezer. You can bet that the cooking process is going to be seriously suspended, and so is the digestive process suspended when cold beverages are drunk. Nerve endings are also numbed by intense cold just as they are numbed by high heat.

Drinking iced water or beverages over ice is a habit that has only been recently acquired by modern man. Why he must have ice cold drinking water from fountains is a mystery. No other animal will drink extra cold or extra hot liquids; they wait until they have reached room temperature.

Remember that the inside of the body is a hundred times more sensitive than the outside. Why should you pour burning or freezing liquids into your stomach? Like many habits, drinking hot or cold beverages seems very silly and abnormal when you look at it in an unbiased way.

### **3.3 Drinking Instead of Nutrition**

Another harmful drinking practice is using beverages as a substitute for proper nutrition. Drinks such as alcoholic beverages and soda drinks are full of empty calories. They supply little nutrition in the diet, but many calories. All too often, children use soft drinks for an energy lift instead of wholesome foods. Adults drink beer or mixed drinks in place of good nutrition.

Concentrated fruit juices are consumed instead of the whole fruit. Milk drinks like shakes and malts are downed in place of a wholesome lunch. It's all too easy to fill the stomach up with needless beverages instead of eating a proper meal.

The problem with many of these beverages is that they so easily become habitual. People drink morning coffee instead of eating fruit for their liquid requirements. They have their soda drink every afternoon or their few bottles of beer. In little time, they have established a beverage habit that has replaced the good habits of nutrition and wholesome foods.

### **3.4 Is Drinking A Natural Process?**

To suggest that drinking may be an unnatural or at least an unusual practice may seem foolish. After all, everybody drinks—or do they?

Not actually. There are some people who go for days or weeks without drinking a single glass of water or taking a swallow of any beverage. These people also eat an abundance of fresh fruits and vegetables which have a naturally high water content and they eat no salt or other thirst-creating spices in their food. Consequently, they get all the fluids they need from fresh foods and never feel thirsty or have the need for a drink of water. This is not speculation or heresay; it is an observation of my own personal experience as well. During the last six months, for example, I doubt if I drank more than six glasses of fluids. I did eat large amounts of melons and many other fresh juicy fruits. These foods supplied me with an abundance of fluids or water from their tissues. Many other people who eat a similar diet of chiefly fresh fruits and vegetables also report little or no need for drinking fluids.

The animals that have the greatest need for drinking are carnivores or meat-eaters. Their high-acid meat diet requires frequent flushing of the kidneys to remove the waste products of the meat, and the concentrated nature of their meat diet usually means they do not get enough water in the foods they eat. These animals have lapping tongues so that they can get the water into the mouth quite easily. Man has no lapping tongue mechanism. He has no snout to put into the water to drink.

In fact, man is so poorly equipped to drink water that he invented the drinking cup so he could move the water in his mouth. The truth is that man has very little natural equipment for drinking. Man is not a drinking animal. To be sure, we can swallow water and we can catch some in our hands for this purpose. When compared to all the other drinking animals, however, man is short on the physiological necessities to facilitate drinking. He is like the ape in this respect—another animal that rarely drinks water in its natural habitat.

This is not to say that we should not drink water. Obviously, there are times when sufficient high-fluid foods may not be available to eat and we will need to supplement our fluid sources from water directly. During fasting specifically is the need greatest for drinking water since no foods are being eaten. Then, too, if we eat a conventional American diet with its high amounts of uric acid, toxins, salt, and other thirst stimulators, we will have to drink perhaps as much as the eight glasses of water a day recommended by certain nutritionists.

But the point is this: if you eat a natural diet high in fresh fruits and vegetables, you will rarely

experience the desire to drink. Usually, when thirst arises and the individual is not in a fasting state or in a very hot environment, then it is due to an improper choice of foods.

[Home](#) > [Lesson 34 - The Harmfulness Of Beverages In The Diet](#) > 4. Drinking Of The Diet

## 4. Drinking Of The Diet

### 4.1 Foods That Cause Thirst

Excessive thirst is caused by eating foods which are either deficient in natural fluids or high in salt, spices or their condiments. A high-protein diet also requires more fluid intake because the waste products of such foods require a large amount of water for their solution and excretion.

Foods become deficient in natural fluids either by cooking or drying them. Cooked foods lose their natural water in the steam that leaves them while cooking. Dried fruits, nuts, dried beans, peas, and other foods which have had their water content decreased by storage or drying are also "deficient" in water content.

The solution appears simple: don't cook fresh foods and they will remain water-sufficient. If dried foods are eaten, they may first be soaked in distilled water or eaten with a compatible, high-fluid food (such as lettuce and nuts).

Most thirst occasioned by foods, however, is due to the salt that is added to them. The body tissues become deprived of water when salt is used. Salt is an irritant to all the cells of the body, and water is used to flush and transport this poison out of the system. This is why extra water is desired when eating salted foods—the body is attempting to remove this biocidal seasoning as quickly as possible.

Other strong spices and seasonings may also bring about a desire to drink. These, too, act as irritants to the delicate tissues of the body, and the water serves as a transporter.

To avoid unnatural and excessive thirst, eat your foods fresh, uncooked, and unseasoned.

### 4.2 The Water-Sufficient Diet

One of the criteria for an optimum diet is that it should also be water-sufficient. That is, a good diet should also supply you with sufficient fluids so that drinking needs are minimal or nonexistent. One reason for this is that the best fluids for your body—the purest and most natural liquids—are the fresh juices of fruits and vegetables *as they exist in the food itself*.

The fluids of fresh fruits and vegetables contain superior minerals and natural sugars. They are easily assimilated and supply all the cells with all the nutrients they require.

By a wise selection of your food, you can supply all your body's fluid needs with the best possible liquids.

Certain vegetarian animals that feed on wild grasses and fruits never drink water as long as they can find their natural food. Generally, these animals live on foods that have about an 85% water content. Mother's milk contains about 87% water, and an infant feeding on this food alone never requires additional water. It appears that as long as foods are eaten which are from 80% to 95% water, thirst will not occur and all the body's water needs will be met in a superior fashion.

### 4.3 The Water-Sufficient Foods

Almost all fresh fruits and vegetables contain 80% to 95% pure water. These foods should form the majority of an optimum and water-sufficient diet.

Other foods may be included, such as seeds and nuts, provided that they are eaten with high-fluid foods in a compatible combination. For example, most nuts are 4% to 5% water. Lettuce is 95% water. If a sufficient amount of lettuce is eaten with a small quantity of nuts (say, 1 ounce of nuts and 8 ounces of lettuce), then a fluid average of 85% is maintained for the meal and thirst will not develop.

It's really not necessary to be so concerned with figures, percentages, and proportions. A simple rule to follow is this: if a natural food is eaten that is low in water content, then it may be advisable to eat a salad, raw vegetables, fruits or whatever is compatible to balance the low-water food. Of course if your meal consists mostly of cooked, refined, or concentrated foods, then it may be impossible to balance them with water sufficient foods.

The optimum diet does not include salt, seasonings, or spices. All of these substances occasion thirst and cannot be utilized by the body.

If you eat an abundance of fresh, raw, unseasoned fruits and vegetables (supplemented by nuts and seeds if desired), then you will be satisfying all your water needs with the highest form of liquids. You will rarely experience thirst, have no desire to drink, and will enjoy the optimum level of health that is the birthright of every human being.

[Home](#) > [Lesson 34 - The Harmfulness Of Beverages In The Diet](#) > 5. Questions & Answers

## 5. Questions & Answers

### How much water or juice should I drink when I fast?

When fasting, you should always slowly sip pure distilled water whenever you are thirsty and drink until you are no longer thirsty. There is no fixed amount to drink or not to drink. You should not force yourself to drink while fasting, nor should you ever deny yourself a drink while going without food. Don't try to "fill up" on water to ease your hunger pains—it won't work.

By the way, if you're drinking juices while fasting, you are not actually fasting. You're on a juice diet. There is nothing seriously wrong with a juice diet, provided that the juices are made and used strictly fresh and that excessive amounts are not taken as a substitute for food. However, to get the benefits of a fast, you have to fast and take only distilled water—not juices.

### Most doctors and nutritionists say we should drink 8 glasses of water every day for good health. What do you say to that?

If you eat what most doctors and nutritionists eat, that might be good advice! A typical American diet is high in salt and animal protein—both of these require copious amounts of water to keep the kidneys flushed and the tissues clean. Few people eat enough fresh fruits and vegetables to supply them with adequate fluids. I have no doubt that a diet of hot dogs, potato chips and ice cream would also require the addition of eight glasses of water per day. But if your diet is healthy, if you include high-water content foods, if you don't use salt or animal proteins, then why flood yourself with water? Drink according to thirst, not by some recommendation or the other.

## **I become thirsty right after I eat, and then when I drink water, I get indigestion. Help!**

You become thirsty after you eat only if you eat cooked foods, salted or spiced foods, or concentrated foods (like nuts). First, give up salted foods. You cannot get around this fact: salt-eating will always give you an unnatural thirst.

If you eat cooked or concentrated food, then you must eat a large amount of water-sufficient foods along with them. This usually means a large raw salad. Make sure you drink some water about an hour before you eat. This may help prevent thirst after eating. Of course if you eat a high-water meal of only fresh fruits or raw vegetables, you should never experience that after-meal thirst—or indigestion, for that matter.

## **I like to make blender drinks. You know, some fruits and nuts and things. Is this an okay beverage?**

Blender drinks are not actually drinks—they are meals that you have first run through a blender. If you have chewing problems, poor teeth, or whatever, then this might be an acceptable compromise in your diet. If you must blend your foods, don't "drink" them—eat them. Use a spoon and eat the blended food slowly, chewing each mouthful as well as you can and mix it with your saliva. Gulping down a blender drink is one way to indigestion. Also make sure that the foods you blend together are compatible foods to begin with. Nuts and fruits may not make an ideal combination in a blender drink. As we said, a drink (if it's not water) is either a food or a poison. Blended up drinks are foods—separate meals—which should be eaten by themselves and immediately after preparing them to avoid oxidation and nutrient loss.

## **What can you say to people when they ask you what you want to drink?**

Tell them you want a big glass of "sky-juice"—water in other words. If you are thirsty, drink it. If not, keep it beside you and don't make a big deal out of drinking or not drinking. For many people, drinking is a social activity and an act of hospitality. If you graciously accept a glass of water with no further discussion, then everyone should be quite comfortable.

[Home](#) > [Lesson 34 - The Harmfulness Of Beverages In The Diet](#) > Article #1: Warning! Don't Use Commercial Juices!

## **Article #1: Warning! Don't Use Commercial Juices!**

Bad enough that anyone should use freshly-pressed pure fruit and vegetable juices instead of the whole fruit or vegetable. But commercial juices are not only fragmented, but contain toxins as well.

What juices do you like? Tomato? Freshly squeezed is pretty bland stuff. The jazzed-up commercial juice always tastes thick and "exciting." Of course the tomatoes used may be ripe, overripe, underripe and even partially rotten since any tomato may be turned into juice. Mixed well, no one knows the difference, especially after pasteurization and salt disguise the flavor.

Do you use commercially squeezed orange, lemon and grapefruit juices? It's the fashion these days to use reconstituted juices. The juices are squeezed from oranges, grapefruit and lemons, peels and all.

The juices from the peels contain citron oil which is quite toxic in the human system.

Citrus trees, like other fruit trees, create a fruit to attract animal consumers. The seed is dispersed in the fruit for propagation by the eater of the fruit. The fruit/seed package is protected until the moment of ripeness by a skin against bacteria and insects. Citrus fruit skins contain citron oil (not to mention fungicides and insecticides) which is an excellent "antibiotic" and is repulsive and toxic to all creatures including humans. Commercial juicers squeeze this toxic juice into the mix with other parts of the fruit. Even the juices of the seed, which may contain hydrocyanide, etc. are pressed into the mix. The juices are then dehydrated and pasteurized. The resulting concentrate is frozen and shipped to points throughout the country for "reconstitution." If you buy frozen concentrate and add water, you're getting the same devitalized stuff.

It doesn't matter if the juices come from cans or frozen concentrates. It's all been heated, refined, conditioned, preserved and otherwise ruined. It deserves to be left on the shelf.

There's no reason why we can't have all the fresh juices directly from the fruit. Most fruits can be shipped just as easily as the juices, although it involves more shipping volume and weight.

Of course this observation is for those that insist on juices—the best of juices are always second-rate to the whole fruit, the natural juice source.

[Home](#) > [Lesson 34 - The Harmfulness Of Beverages In The Diet](#) > Article #2: No Teas For The Hygienist

### **Article #2: No Teas For The Hygienist**

The practice of drinking teas made from the leaves, the stems, barks, roots, flowers, seeds and fruits of plants is an old one. The practice was taught to mankind by the medical profession, which was, in its origin and for long after its origin, largely herbal in character. Due to the fact that some part of almost every plant contains a poison or two, it is possible to use some part of almost every plant known to man for its alleged "*medical action*," both for the "*prevention*" and "*cure*" of disease. Faith in the healing virtues of herb teas lingers on in the minds of the people long after the medical profession, which originally fostered and cultivated this faith, has abandoned it.

Mint tea, alfalfa tea, horse mint tea, and other teas are in extensive use among a growing segment of our population and great numbers of these people are convinced that they can derive benefit from the practice of drinking these teas. A brief, instructive reference to some of these currently popular teas is given below, in *Herbal Myths*.

*Reprinted from The Hygienic Review, August 1973*

[Home](#) > [Lesson 34 - The Harmfulness Of Beverages In The Diet](#) > Article #3: Herbal Myths

### **Article #3: Herbal Myths**

Juniper berry tea is "healthful, adding fluorine to the diet, increasing functional activity and increasing the secretion and flow of urine"—all of this means that it is a stimulant and that the kidneys are forced to expel it quickly.

Parsley tea has a "purifying action" and is a "diuretic" and "mild sedative."

Papaya tea is a "fine tonic," has a "rebuilding effect on the stomach and digestive tract," and contains a "digestant" that is "capable of digesting many times its weight in protein food." If you could find other "digestants" to take care of the other food factors, you could dispense with the secretion of digestive enzymes.

A delicious combination of lime leaves and papaya that you will always use, once you have tasted it, is sold to the public.

Then there is red clover tea which is "beneficial to the bloodstream" (a "blood purifier") and "cleansing to wounds, boils and ulcers."

Chamomile tea has a "soothing effect on the nerves and stomach" and is regarded as excellent for children.

Just plain lime tea, without the addition of papaya, "acts on the nervous system, allaying nervous excitement, invigorating and strengthening, and also soothing and relieving inflammation."

Horse tail herb tea is "invigorating and strengthening." It is an "alterative" and an "astringent."

In spasms, mistletoe tea is said to "relieve nervous excitement." (MISTLETOE IS ALSO POISON—See Article "Plant Products And Effects" in Lesson 33).

Then there is blueberry tea, an "exciting beverage with delicate fragrance," made from the leaves of the blueberry, which "purifies." It is an "antiseptic, a blood purifier and it soothes."

Strawberry tea, made from the leaves of the strawberry, "provides many benefits to the urinary organs." It is "astringent, tonic, diuretic, a bitter alterative."

Sassafras tea, an "old favorite," is described as a "wonder drug." It is a "blood purifier" and an "aid to the skin"—at least, it is said to be.

Fenugreek tea seems to be one of the present day favorites. If we are to believe the advertising, great and increasing numbers of people are drinking this mild poison regularly. This tea "soothes minor irritations of the stomach and intestines, softens and soothes inflamed parts and relieves inflammation. It is also good for those with excess mucus due to dietary errors." I presume that you take this tea instead of correcting your dietary errors.

Mate, a caffeine-containing tea from South America, is highly praised because it "gives a pick-up like coffee." Why not? It contains the same poison.

Desert herb is an old Indian tonic, often called squaw tea. Although almost all the medicinal virtues are attributed to this tea, it is listed only as "alterative, depurative and diuretic."

Hop tea is both a "tonic" and a "sedative"—stimulates and inhibits—and is used for "relieving pain, allaying nervous excitement, and to abate fever."

Flaxseed tea "relieves coughs and sore throats, painful urination and bladder inflammation. It is also good in dysentery."

Sarsaparilla tea, an old-fashioned favorite, "purifies the blood and is used for affections of the chest." Used for coughs for countless generations, it is "aromatic, depurative and alterative."

Alfalfa tea is said to be especially valuable in rheumatism and arthritis. It is chiefly recommended for its "richness in minerals." When mint is added to the alfalfa, this provides a delicious tea that gives all the "advantages" of the alfalfa plus the "sedative effects" of the peppermint leaves and the "aid" they give to digestion.

Nettle tea is a "diuretic" that has varied "properties." Besides "increasing the secretion and flow of urine" (meaning the kidneys hurriedly eliminate it) it is "excellent for the circulation," is a "tonic" and "relieves infections of the chest."

For your constipation here is a "pleasant" herbal laxative that should be every bit as good as Inner Clean, Hood Lax, All-Lax, NR Tablets, Black Draught, or anything that grandmother used to brew. It is a curious combination of "freshly cut senna, mandrake root, boneset leaves and tops, elder flowers, sassafras bark, peppermint leaves and Mexican saffron." Use this compound and "keep free from annoying symptoms arising from a constipated condition."

Finally, here is a "tasty tea" made of a blend of alfalfa, peppermint and desert herb, which you are sure to like, once you have tried.

Dock root "purifies the blood and strengthens in a permanent manner, both allaying and preventing scurvy." It is also an "astringent."

Certainly from this list of drugs with their astringent, alterative, tonic, diuretic, digestant, soothing, sedative, purifying, emetic, laxative, etc. "actions," you can find one or more that "will help you back to good health, even assist you in retaining good health." If you read over the classifications of the alleged actions of these teas and fail to recognize the fact that they are *drugs* and are "recommended" as such, this is because you are unacquainted with so-called pharmacology and the herbal *materia medica*. They employ the technical jargon of allopathic medicine in describing the "effects" of their teas. What is a depurative, for example? It is "a drug for aiding a cleansing process." An alterative is a "medicine" that "alters the processes of nutrition and excretion." Such a drug is supposed to be capable of "restoring the normal body-functions." A diuretic is a "medicine" that "increases the flow of urine." How does it increase the flow of urine? Does it assist the kidneys? Does it add to the functioning power of the kidneys? It does neither of these things. *It is a poison that is hurriedly eliminated by the kidneys.*

Herbs are nature's own products, we are assured. We could reply that rattlesnakes and cobras are also nature's own products. They come to you "entirely natural." I can hear the hiss of the rattlesnake as he strikes: "My venom comes to you entirely natural."

Teas are made in two general ways. They are prepared as *infusions* and as *decoctions*. An infusion is the solution obtained when a substance is steeped in water to obtain its soluble principles. It is an old medical device used to extract the "medicinal" qualities of herbs. A decoction is a substance derived by the process of boiling. This is also an old medical device used to extract the "medicinal" qualities (the poisons) from herbs. Infusions are made by pouring hot water over the tea and permitting it to steep. Leaves, flowers and thin materials are prepared as infusions. Decoctions are made of the harder materials, such as barks, roots, chips, seeds, etc. These are boiled to extract their "soluble principles." An aromatic is a substance with a spicy fragrance. Such substances are said to be "stimulating," but they are often added to infusions and decoctions to make them acceptable to the sense of smell.

I shall not, at this time, consider all the alleged actions of these various teas. Enough has been said to reveal that they are recommended to the public as drugs and because they are supposed to have *therapeutic actions*. All such actions are actions of the body and are employed as means of freeing the body of offensive substances. An herbal laxative is laxative because of the laxative action of the *bowels* in expelling the herbs or the tea made from these. These are expelled because they are *poisonous*. It does not matter that there may be minerals and vitamins in the herb or tea; the very hurry to expel them from the body prevents their digestion and absorption. Nonpoisonous herbs are foods; poisonous herbs are supposed to be "medicine." Do not permit yourself to be misled by the assertion that "current research is proving the value of teas, herbs and berries used in Grandma's day." Research seems to be able to prove anything it is *paid* to prove.

Review the Articles in Lesson 33: *Natural Foods—They refer to them as "healthy," but some are actually hazardous and Plant Products and Effects.*

## Article #4: The Stimulant Delusion

Some time ago, a magazine published by a religious organization came to my desk. It contained an article which traces chocolate from seed to candy bar. It opens by saying that "chocolate in its many forms has been a taste delight of millions." It ends by saying: "Many have come to know the nutritional value of chocolate as well as enjoy it for its taste when mixed with sugar. The Creator has thus provided for his Creatures an unending variety of foodstuffs to sustain them and gratify their varied appetites."

In between these two asinine statements is a brief story of the planting and cultivation of the Cacao tree, the harvesting of its crops and the preparation of the cacao beans for the factories. In the whole article there is not one word said about the poisonous quality of cocoa, nor does the article even hint that the sugar with which it is mixed is white sugar.

The thought comes to me that if the Creator prepared this substance for the use of His creatures, He might well have left the poison out of it. The article does say that the chocolate is bitter, but it fails to mention the fact that, without the addition of great amounts of sugar, the stuff is so bitter that none of the "varied appetites" of man would relish it. It is only by so thoroughly disguising its true character, as manifest in its taste, that foolish men and women can get the poison substance past the sentinel of taste.

Arguments such as that given in the magazine article can be made to sustain any vice or practice to which man may be addicted. We may assume that the Creator made tobacco to satisfy the varied tastes of man, or that he made opium for the same purpose. There is actually more nutritive value in the leaf of the tobacco plant than in chocolate. People do not eat chocolate for its alleged nutritive value but for its *stimulating* quality. The *theobromine* of chocolate is identical with the *caffeine* of coffee and the *theine* of tea. It is simply a poison and there are no conditions or circumstances under which it should be taken into the human body. Theological defenses of poison vices are always misleading.

Coffee, tea, cocoa, chocolate and the caffeine-containing soft drinks should be classed together and it should be fully recognized that they produce evil and evil only, when introduced into the human system. None of these vices is very old but each of them is very wide-spread. People swallow these poisons under the delusion that *stimulation* is somehow beneficial.

Of coffee we read in medical literature that, "While a certain portion stimulates the nervous system, a large portion acts as a sedative, so that a difference in the quantity of the potion causes a difference in the kind of its effects." It is impossible to explain this apparently contradictory behavior of coffee on the basis of the medical theory that "drugs act." If caffeine is a *stimulant*, why is it less of a *stimulant* in large than in small doses? Indeed, why does it not *stimulate* in proportion to the size of the dose—why aren't large doses proportionately more *stimulating* than small doses? Why does it apparently act the exact opposite in large doses from the way it acts in small doses?

We can find our answer only if we realize that the increased action that we designate *stimulation* is simply the extra effort exerted by the body in expelling the poison. This being true, and it is, so-called *stimulants* must necessarily and inevitably deplete the body's powers in proportion to the expenditure their use occasions. Because the sick person is already greatly depleted, he is less able to bear the losses occasioned by the use of stimulants than is the well and vigorous individual.

Of theine, it is said that when given in small doses to either animals or man, it "quickens the circulation," and "effects some degree of mental exhilaration and wakefulness." But the "final result" is diminished excretion of carbon-dioxide—"the flow of blood through the capillaries is retarded." Large doses "prove poisonous, causing painful restlessness, rigidity of the muscles, and general exhaustion."

Thus, theine is pictured to us as a *stimulant* in small doses, a "poison" in large doses. What is there in the size of dose to change the character and quality of the substance? In what way does the size of the dose alter its relation to the vital structures? As soon as it is realized that *stimulation* is excited action in resisting and expelling the small dose, it will be recognized that the drug is a poison in doses of any and all sizes.

- [Article #2: Junk Food Diet Result In Disease By Susan Hazard](#)
- [Article #3: Food In Your Poison By Viktoras H. Kulvinskis](#)

### 1. What Is Junk Food?

By junk food we mean foods that have been so altered and impaired in the process of manufacturing, bleaching, canning, cooking, preserving, pickling, etc., that they are no longer as well fitted to meet the needs of the body as they were in the state Nature prepared them.

Let's face it, we can't improve upon Nature! But people still insist on trying and the results are disastrous. When we attempt to alter any food by adding or subtracting components or by heating or freezing, we are degrading that food to the extent to which we alter it. Nature prepared our foods perfectly suitable for our consumption in their whole unchanged state. When these food items are changed or altered in any way, they become denatured junk. Disease is the inevitable result from eating such foods.

#### 1.1 Foods Must Be In Their Whole State

Numerous animal experiments have shown that, while proteins, carbohydrates and fats are food elements, they are not in and by themselves food. Junk foods usually contain excessive amounts of the above named food constituents and little else. For example, candy would be almost purely carbohydrate. Butter (according to our definition this is a junk food) would be a pure fat.

It has been established that a diet that contains enough nourishment, by all the recognized chemical standards, still fails to support normal growth and physiological normality, if it lacks some unknown substances. Very little of these substances need to be present, but there is an irreducible minimum. This would consist of the many vitamin and mineral elements, enzymes, etc. which are only available in usable form in whole raw fruits, vegetables, nuts and seeds.

The refining, preserving and cooking processes to which our foods are subjected destroy the delicate constituents in our foods. In fact, the cooking process robs foods of so much of their value that most people feel that they must add salt, spices and various condiments to them to make them palatable.

#### 1.2 Food Constituents Must Be Organic

We need to consume our food in its whole state, for in this form we can readily assimilate all the nutrients which we derive from that food. When foods are fragmented and certain vitamins or minerals

are added in an inorganic form, that food loses its value. Any food so deranged is truly a junk food.

The addition of one or more vitamins to such denatured foods would not render them adequate.

Vitamins and minerals never work independently of each other but synergistically for the benefit of the whole organism. When there is either a lack of calcium or an excess of acid in the food, Vitamin A has no effect. It is known that mineral salts are not assimilated in the absence of the vitamins and both are spoiled by cooking. Most junk foods (if not all) which are commonly sold in stores have undergone some cooking.

Minerals which are returned to the junk foods are inorganic and therefore unusable by the body. Sodium chloride, for example, is not assimilable or usable by the body. It is excreted unchanged. It comes out in the same state it entered the body. No metabolizable food does this. Sodium chloride is not a food but an irritant. This is true of all inorganic minerals and salts. They are useless, supply the body with nothing and are toxic.

Dr. Shelton says, "We have not learned to make, nor even to imitate living substances. We know that animals are dependent upon plants for their food and cannot go directly to the soil for it. We can neither synthesize these substances in the laboratory, nor can we tear them down in the kitchen or in the laboratory in "purifying" them (extracting their salts from them) without greatly impairing their food values."

Nature gave us apples, pears, cabbage, celery, lettuce, oranges, nuts, etc. and not vitamins, minerals as such. All our food needs are found in neat little packages and when consumed in this form, we do not have to concern ourselves with food deficiencies. All of our needs will be met most adequately.

[Home](#) > [Lesson 35 - Junk Foods: A Case Study On Molasses](#) > 2. Molasses: A Super Junk Food

## **2. Molasses: A Super Junk Food**

Molasses is a prime example of a junk food. This is a product which has been so degraded that it really should not be called a "food" at all. It has been refined, processed, contaminated with poisons and boiled to such an extent that it could never be of any benefit and, in fact, will contribute to toxicosis if ingested.

So let us take a look at this "super junk food."

### **2.1 What Is Molasses?**

Molasses is a yellowish or dark-brown, thick, sweet, sticky syrup which is most often used for cooking, candy-making or as a livestock feed. Most molasses is obtained as a by-product in the manufacturing of sugar from sugar cane but some is obtained from the sugar beet. Therefore, countries that grow sugar cane produce most of the world's molasses. In the United States, Louisiana is the center of molasses production.

Molasses contains 36 to 50 percent sugar. Chemists and drug manufacturers use it to make many chemical products, including industrial alcohol. Molasses yields large amounts of citric acid. This citric acid from molasses is used in making soft drinks. Low-grade molasses, called blackstrap, is fed to livestock.

Molasses that is to be eaten contains much sugar, so it tastes sweet. It is often used in making cookies and candy for the unusual flavor which it imparts.

## 2.2 How Molasses is Produced

In preparation for harvesting the sugar cane, the fields are set afire to burn off the dried up leaves. Then the sugar cane is cut down and taken to the sugar refinery. It is put through high-pressure rollers to squeeze out the juice. The juice contains many impurities including field soil, cane fiber and wax, organic acids, ash, nitrogen compounds, pectin and gum. On the other side of the vat containing the juice is the resulting fibrous tissue, called bagasse.

The bagasse is further processed to get the ultimate sugar content out of it. It is sprayed with super-heated hot water which quickly saturates the bagasse and picks up, in solution, more sugar. It also picks up some of the pulpy organic matter.

This is then squeezed out of the bagasse by yet another set of high-pressure rollers. It is cooled and combined with the original juice. This diluted juice contains less sugar than the virgin pressing. Also, it contains a lot of organic matter or pulp.

To get crystalline sugar from cane juice, the first step is to stabilize it chemically so that its prized content, sucrose, will not become invert sugar, that is, fructose and/or glucose. Cane juice has a pH of about 5.4, which is on the acid side, and the first boiling would cause the sucrose to break down into its two basic sugars, fructose and glucose. As a stabilizer, about five gallons of liquified quicklime is added to 1,000 gallons of juice. This gives it a pH of about 8.0, thus stabilizing the sucrose. Also added at this stage to clarify the liquid are sulphur dioxide/carbon dioxide and, usually, phosphoric acid.

Then the juice is put through its first boiling to remove most of its water and to obtain the first extraction. What remains from this first extraction is called crude molasses. Then more chemicals are added to the residue and yet another cooking (boiling) is done. Acid sulphite and carbon compounds are added.

After this extraction comes yet another extraction during which bone char (cattle bones that have been heated to the point of charring), sulphur compounds and chlorine are used as clarifiers and purifiers. Chlorine is used for its "bleaching" action.

The final residue is called molasses.

## 2.3 Molasses Contains Sugar

As you have learned from previous lessons, refined sugar of any kind has devastating effects on our health. Such sugars are responsible for many diseases and disorders including tooth decay, obesity, heart disease, hypoglycemia, diabetes, meningitis and many others.

You have also learned that when you eat any refined carbohydrate, the body must take vital nutrients from healthy cells to metabolize incomplete foods. Thus, sodium, potassium, magnesium, and calcium are drawn from various parts of the body to make use of the sugar. Likewise other valuable vitamins, minerals and enzymes are robbed from the body.

Since molasses contains 36-50 percent sugar, the known harmful effects of white sugar would also apply to molasses.

[Home](#) > [Lesson 35 - Junk Foods: A Case Study On Molasses](#) > 3. Harmful Chemicals In Molasses

## 3. Harmful Chemicals In Molasses

Most of the chemicals which are used in the refining process of cane sugar eventually find their way into

the waste residue which is the molasses. Therefore, you not only have the harmful effects of the sugar but also of the toxic chemicals which are used in its manufacture. We will take a look at some of the chemicals.

### 3.1 Sulphur Dioxide

Sulphur dioxide is a chemical compound of sulphur and oxygen, having antioxidant properties. It is sometimes used in food for control of discoloration.

An antioxidant is a substance that prevents or delays oxidation—a substance capable of chemically protecting other substances from uniting with oxygen. It is one of the most common groups of additives used to prevent change in color or flavor caused by oxygen in the air. For example, some fruits and vegetables containing certain enzymes (such as apples, apricots, bananas, cherries, peaches, pears and potatoes), darken when exposed to air after being cut, bruised, or allowed to overmature.

According to the Merck manual, exposure to sulphur dioxide results in respiratory tract irritation: sneezing, cough, dyspnea, and pulmonary edema when inhaled as in smog. If the body responds so strongly to this agent when it is in the air, it makes sense that it cannot tolerate it when we ingest it with our food. It is, in fact, a deadly poison and is treated as such in the manual.

Everyone knows that we need oxygen to live; in the absence of oxygen we cannot breathe. On a cellular level our cells require oxygen to function. All plants and fruits of plants contain oxygen as an essential component of their structure. Oxygen also plays a role in every action and reaction in our body and is required to produce the ATP (adenosine triphosphate) for energy metabolism.

Oxidation may be interpreted in several ways. The addition of oxygen to a molecule is one form of oxidation. Every oxidation must also be accompanied by the opposite reaction, a reduction, and this is when oxygen is taken away or reduced from a molecule.

Oxidations and reductions are essential in utilization of foods to provide energy. The oxidation of foodstuffs, fats, carbohydrates, and proteins, takes place in a step by step manner through what is called the "Kreb's cycle." The end result of the Kreb's cycle is liberation of energy to be used as needed by the body.

Any interference at any point during the oxidation reduction process can and does effect the entire body. Research is lacking on what effect antioxidants which are added to our food can have on general cellular metabolism but as students of Life Science you know that any fragmentation of our natural foods always results in adverse consequences. Especially serious consequences occur when out and out poisons are added to our food, such as sulphur dioxide.

- Must be digested efficiently.
- Must have protein adequacy.
- Must have vitamin adequacy.
- Must supply mineral salts amply.
- Must supply our needs for essential fatty acids.
- Must supply our needs for caloric values.

Does molasses meet any of these requirements?

Molasses is the end product in the manufacture of refined sugar. It contains many toxic substances. Psychologically, this dark goeey product has no appeal at all except that we have become accustomed to it and have learned to accept it as an addition to our diet along with other perversions. Children naturally rebel against the taste of molasses. This does not occur with a nice ripe banana or a piece of watermelon, for example.

Molasses is not delicious to any unperverted palate. Furthermore, molasses has no natural state since Nature never created such a conglomeration of sugar and chemicals. Molasses has no living state in

Nature. It is repulsive to our sense of smell, taste and sight. Molasses is not easily digested. As little as one tea-spoonful will result in nausea. This indicates that the body rejects this poison rather than attempting to digest it as it would with a normal food such as an apple.

Molasses is not digested efficiently. It is often passed through the body with little absorption and often results in diarrhea. This is another indication that the body is attempting to dispose of this toxic matter.

Molasses is entirely lacking in protein.

Since molasses goes through such a long boiling process, there are no vitamins left in the end product. The only mineral salts that are detectable in molasses are those inorganic minerals that are residues from the contaminants accumulated during the manufacturing process. These inorganic minerals are not usable and are toxic.

Molasses supplies no fatty acids.

One tablespoon of blackstrap molasses supplies approximately 43 calories. In order to meet our daily caloric needs, we would have to consume an entire meal of molasses. Molasses cannot be relished by itself by anyone. A proper food of humans can be eaten as a meal. For instance, we can make a mono meal of any one of these foods: apples, watermelon, cantaloupes, bananas, grapes, oranges, peaches, apricots, figs, dates, etc. And you can maintain health for several weeks just on these foods alone. However, you could never make one mono meal of molasses. It would be repulsive to even think of doing so and it could certainly not support life.

The fact that molasses cannot meet any of the criteria of a food automatically puts it in the category of junk food and it should be eliminated from our diet forever!

[Home](#) > [Lesson 35 - Junk Foods: A Case Study On Molasses](#) > 4. Health Claims For Molasses

## **4. Health Claims For Molasses**

### **4.1 Minerals in Molasses**

Dr. Rudolph Ballentine says that, "Since it is a concentrated residue, molasses contains significant quantities of minerals such as iron, a fair amount of calcium and generous quantities of trace elements such as zinc, copper, and chromium."

Just because these minerals can be detected in molasses does not mean that they are in a form that can be utilized by the body. In fact, these minerals are mostly resulting from the residues from the lime, cattle bones, soil, and other residues left after being boiled for many hours at high temperatures. Most are inorganic and totally unusable to the human body. Even if there were any organic minerals left, they would be rendered useless after the boiling and chemical treatment.

### **4.2 A Rich Source of Vitamins**

It is claimed that the chief value of molasses lies in the fact that it is rich in vitamins of the B family. Considering the process which the molasses has gone through, this is quite impossible. First of all, the B vitamins are water soluble. Large quantities of water are added to the molasses during its manufacture. So the B vitamins would be dissolved. Second, B vitamins are destroyed by heat at even a moderate temperature. They are certainly destroyed by the high heat and long boiling time required in the process of rendering molasses.

### **4.3 Molasses - A Good Laxative**

The fact that the consumption of molasses results in diarrhea or seems to have a laxative effect is proof that the body is attempting to dispose of this unwholesome food as quickly and as best it can. It is completely incompatible with bodily needs or functions.

P.E. Noris writes, "At night take a teaspoonful of molasses in warm water or milk." He cautions that one should not take more than this as it may nauseate you. His body is trying to tell him something but he is not listening. The body knows what is a poison and what is not. Take a tablespoon of any wholesome food such as sunflower seeds. You will feel fine and most likely will want more. Take a tablespoon of molasses and you will be immediately sick. There will be no craving for more.

Do yourself a favor and do not poison yourself.

You should also be aware of the fact that this poison is not only added to molasses but is often seen in most dried fruits. As you know, dried fruits are valuable additions to our diet when they are of good quality. However, when treated with sulphur dioxide, these fruits become deadly as the poisons with which they are treated and should never be consumed.

How can you recognize sulphur treated fruits? Mostly by the color. If the fruit's color is bright and unusually clear, it has been treated. If the fruit's color is dull and a little brownish, then most likely it has not. Also, read the labels when buying these packaged dried fruits. Another excellent idea would be to dry your own. Home food dehydrators are readily available and do an excellent job of drying and preserving fruits. This way you know for sure that the fruit was of excellent quality and no poisons were added to them during the drying process.

### **4.4 Carbon Dioxide**

Carbon dioxide gas is generally produced in the combustion, decomposition, or fermentation of carbon or its compounds, is found in the air and is exhaled by all animals. It is the final product of combustion of carbon in food, which the body exhales through the lungs or eliminates through the kidneys in urine, or in perspiration through the skin. Although carbon dioxide is present in the air we breathe (up to about 5%), if it is in a greater quantity than this, it produces an uncomfortable degree of hyperpnea with mental confusion and will cause death by suffocation.

Carbon dioxide gas is used in the manufacture of molasses, carbonated drinks and commercially used in dry ice.

So we know that carbon dioxide is a waste product given off by the body. We also know that if inhaled in large amounts it can result in death. We do not as yet know what effects it will have when added to our food in small quantities. Should we take the chance? As Hygienists we cannot condone the use of proven or unproven poisons. We may assume, however, that if it is poisonous in one form (air), it will also be poisonous in another (food).

### **4.5 Phosphoric Acid**

Phosphoric acid is not only used in the manufacture of molasses but is also added to carbonated soft drinks. It is a solvent which is used to keep all the constituents in a compound in a liquid form. This acid, according to the Merck manual results in corrosive burns from inhalation, skin contact, eye contact, and ingestion. It will also cause local pain. This is another deadly poison.

### **4.6 Bone Char**

In order to understand why this substance, which is added to certain foods including molasses, is dangerous, we must understand what it is that we are dealing with. Bone char is the charcoal remains of animal bones. Charcoal is actually the carbon remains after burning or heating these bones. Carbon is a

chemical element which is present in all organic substances. These include proteins, carbohydrates, and fats.

When a compound containing carbon combines with oxygen in the body, energy is liberated and carbon dioxide is formed. Carbon has several chemical features that make it unique as a foundation for life. However, if these features are altered drastically as they are upon the addition of heat, disastrous results may occur. It is a known fact that the charcoal formed on charcoal broiled steaks which are so commonly eaten today are carcinogens. It is also possible that the alteration of the carbon element in a cooked foods could have adverse consequences on our health. The addition of bone char to molasses just taking this product one step further down the ladder of the junk food dungeon.

## 4.7 Chlorine

Chlorine is commonly used as a water purifier and bleach. Added to flour at 400 parts per million, it instantly ages the flour and bleaches it white. For many years a flour bleach called Agene was used, until England's Dr. Mellanby discovered that Agene caused running fits and mental deterioration in dogs. The Food and Drug Administration, under public pressure, finally outlawed the bleach. But the chlorine bleaches used today, although regarded as safe by the FDA, are highly toxic poisons. Nitrosylchloride, for example, is a very corrosive reddish yellow gas which is intensely irritating to eyes, skin and mucosa. Inhalation may cause pulmonary edema and hemorrhage. Yet this is added to foods.

[Home](#) > [Lesson 35 - Junk Foods: A Case Study On Molasses](#) > 5. Impurities In Molasses

## 5. Impurities In Molasses

Molasses contains 9% ash and 17.5% waste. That consists of mostly cellulose plus all of the wastes left over after the processing of white sugar including soil, residues and chemical contaminants.

So molasses is worse than refined sugar as it carries with it all the bad qualities of refined sugar *plus* the added toxins. As Life Scientists, we attempt to build health and not destroy it. When we ingest such a totally unwholesome and anti-life product as molasses, we are truly destroying life. Do your body a favor and do not give poisons but give it fuel for life in the form of whole fresh fruits, vegetables, nuts and seeds.

Instead of satisfying our craving for sweets with such poisons as molasses, use fresh or dried fruits and your sweet tooth will surely be satisfied.

[Home](#) > [Lesson 35 - Junk Foods: A Case Study On Molasses](#) > 6. Molasses Is Not A Food

## 6. Molasses Is Not A Food

As Hygienists we know that there are several criteria that a substance must meet before we will regard it as a food. Molasses does not meet any of these criteria and we shall see why.

First of all, it might be helpful to review the criteria food must meet to be considered natural and therefore acceptable in our daily diet. Our natural food:

1. Must be nontoxic.
2. Must have aesthetic or sensory appeal.
3. Must be relished in its natural raw state as taken in nature.
4. Must be digested easily.

[Home](#) > [Lesson 35 - Junk Foods: A Case Study On Molasses](#) > 7. Questions & Answers

## 7. Questions & Answers

**I realize that molasses is almost 50% sugar, but wouldn't it be better to consume this product than pure sugar? After all, 50% is better than 100%!**

The fact that molasses contains up to 50% sugar is not its only bad point. The fact that it contains so many other poisonous contaminants, some of which may be carcinogens, is the main reason to stay away from this product. Also, if you are eating a diet of mostly fruits with vegetables, nuts and seeds, additional sweeteners are not necessary or desirable.

**I am convinced that the Hygienic diet is best for overall health and I have been on a raw foods program for six months and feel great! But the problem is that my children love junk foods—especially candy, ice cream, cookies and other sweets. How can I get them away from these awful foods?**

Congratulations on your wise decision to change to a more healthful diet. Apparently your children crave sweets and this is natural—we all do. The problem is they are satisfying their sweet tooth with the wrong kind of sweets. First of all, try to not have any of the junk food that you mentioned in your home. Second, replace it with more healthful sweets like fresh fruits and some dried fruits. When one of your children asks for candy, give him some Barhi dates instead, or any other kind of dried dates or figs. I am sure that your children will love them and it will certainly satisfy their sweet tooth.

**My mother always gave us molasses to eat. She mixed it with some milk and said that it was a good "tonic". I always hated the stuff! Does molasses possess any health benefits?**

No, it is a common misconception that molasses possesses health benefits. No food, even the most healthful, has the quality to act, for it is the body which acts upon the food. There are no benefits in eating molasses and, in fact, only harmful results follow its ingestion. The fact that your sense of taste found this "tonic" repulsive is one clear indication that it should not be eaten.

[Home](#) > [Lesson 35 - Junk Foods: A Case Study On Molasses](#) > Article #1: Denatured Foods Destroy Life by Alfred W. McCann

### Article #1: Denatured Foods Destroy Life by Alfred W. McCann

Animals, human or dumb brutes, die when their food is debased, but the very number of such foods

makes it impossible for an individual to go before a grand jury with the charge: "This food killed my little girl."

For months, perhaps for years, one juggled food brought substances to her diet which her little body could not use. Her vitality in throwing off the excess baggage was slowly sapped.

She was not poisoned by any particular food. A combination of inadequate foods merely robbed her tissues of their tone.

Another food from another source had been processed in a manner that removed some or all of its most indispensable elements. In its refinement it withheld from her little frame the very materials she required for growth, materials that God had elaborated for her, but which unnatural practices had withdrawn from her reach on the vain assumption that it is not necessary to credit the Creator with a profoundly conceived and marvelously executed scheme of biochemic balances and harmonies.

Persistently, month after month, the disordered combination of artificial foods sallied to the dinner table, where all the forces of outraged nature were called into battle with the unseen enemy of health and life.

Commercial expediency looked on as the fight was waged with nature but nature had been equipped with poor fighting materials and the child's resistance, broken at last by the combined attack of unsuspected enemies, buckled, snapped and was gone.

There is no pathologist, no public prosecutor, no father or mother who can accuse the food industry of her death. Let this be fully understood.

Before we can correct a single refined food abuse, by law, we must produce in court the body of a dead child, and prove that life was destroyed by a particular food.

Scientists will be on hand to testify in behalf of the defendant. Food manufacturers have been paying scientists for twenty-five years to testify in their defense.

I have listened on hundreds of occasions to their testimony in adulterated food cases, and in many instances I have seen their sophistries fail, but the facts have rarely been reported to the public.

The fear of advertising losses, as we have seen, has closed the columns of most newspapers and magazines to the truth.

Foods that kill mice, rabbits and guinea pigs are not "harmful" to the child in the law's eyes, for the reason that nobody is willing to feed a child on an exclusive diet of such things until it dies, in order thereby to produce as evidence, a dead body in court.

However, when it is argued that chickens or other experimental animals are not human beings, and that therefore any deductions based on barnyard phenomena are unwarranted when applied to humanity, we are not confined entirely to animal experimentation for our facts.

The same facts have been established in most startling and dramatic fashion, hundreds of times, upon human beings.

In Billibid Prison, Phillipine Islands, 1912, twenty-nine criminals under sentence of death were fed exclusively on refined and denatured foods of the kind most common in America for the purpose of determining the effect of such diet.

Their chief food consisted of polished rice. In six weeks the condemned men became anemic. Their first symptom was slight edema (water-logging or swelling) of the feet and ankles which disappeared after lying down. Puffiness beneath the eyes, with general weakness and pains in the legs, soon followed.

Later the edema became massive, involving even the thighs. Then came marked apathy with muscular wasting and extreme pallor. Finally, an enlargement of the heart with feeble heart action.

It is noteworthy that the symptoms of war-edema reported among German, French and British soldiers, 1916-1918, are identical with these.

Commenting on the Billibid experiments, Drs. R.P. Strong and R.C. Crowell stated: "These diseases developed owing to the absence of some substance or substances in the diet necessary for the normal physiological process of the body. Without a supply of such substances in the food sickness results." This comment in all its vagueness disclosed the poverty of food knowledge possessed by the medical profession six years ago.

The prisoners fed on the denatured diet mingled freely with the other prisoners but there was no tendency of the disease to spread outside the group fed on the polished rice.

When this denatured food was removed from their diet and whole natural brown rice restored to them, they recovered promptly.

In the near future, depending upon the rapidity with which the truth is spread, it will not be so difficult to prove with evidence that cannot be controverted that a murder was committed by depraved food.

[Home](#) > [Lesson 35 - Junk Foods: A Case Study On Molasses](#) > Article #2: Junk Food Diet Result In Disease by Susan Hazard

### **Article #2: Junk Food Diet Result In Disease by Susan Hazard**

In recent years, there has been an increased consumption of meat, refined foods, highly processed and packaged foods with assorted additives and preservatives. This practice has resulted in a marked increase in many chronic and degenerative diseases. The table below demonstrates the serious impact these harmful foods have on our society as a whole.

#### **Nutrition-Related Diseases**

Heart and vasculatory	Over 1,000,000 deaths in 1967
Respiratory and infectious	82,000 deaths per year
Mental health	2.5 percent of population of 5.2 million people are severely or totally disabled, 25 million people have manifest disability.
Infant mortality and reproduction	Infant deaths in 1967—79,000
Early aging and lifespan	49.1 percent of population, about 102 million people have one or more chronic impairments
Arthritis	16 million people affected
Dental health	44 millions with gingivitis; 23 million with advanced periodontal disease;

	22 million edentulous persons; 1/2 of all people over 55 have no teeth.
Diabetes and Carbohydrate disorders.	3.9 million overt diabetic; 35,000 deaths in 1967; 79 percent of people over 55 with impaired glucose tolerance.
Obesity	3 million adolescents; 30 to 40 percent of adults; 60 to 70 percent over 40 years.
Alcoholism	5 million alcoholics;
Eyesight	48.1 percent or 86 million people over 3 years wear corrective lenses; 81,000 become blind every year.
Allergies	32 million people (9%) have allergies
Kidney and renal failure	55,000 deaths from renal failure 200,000 with kidney stones
Muscular disorders	200,000 cases
Cancer	600,000 people developed cancer in 1968 and the numbers increased drastically every year since

## **Eliminate Junk Food For Better Health**

It is well known that heart disease, stroke, cancer, diabetes, arteriosclerosis, and cirrhosis of the liver are among the leading causes of disease in the United States today. What we must do is to remove the cause behind the cause. What caused the heart disease, stroke or cancer? As Hygienists we know that the underlying cause of all disease is toxicosis. But now we must ask ourselves another question. What caused the toxicosis to develop? Well, it could be a number of factors. But one of the main culprits is the junk food in our diet.

During a session of the Select Committee on Nutrition and Human Needs, Senator Charles H. Percy of Illinois stated that "experts have found enough incriminating evidence to conclude that our super-rich, fat-loaded, addictive and sugar-filled American diet is sending many of us to early graves unnecessarily." He says that simple changes in the diet will product positive results in good health and agrees that this would be a far better choice than spending money for medical care.

## **Cellular Health Depends Upon The Quality of the Nutrients**

The immune system, the blood, the fluids which bathe the tissues can be markedly influenced by the nutrients available to the body. In other words, the health of all our cells and tissues depends upon the quality of the nutrients which are available to them. When these nutrients have become altered or destroyed through processing, refining, cooking, etc., the health of the cells within the entire organism will decline as a result.

## **The Body Responds**

The body responds to all influences and deals with them as they arise. When we consume food which is laden with contaminants such as artificial preservatives and other additives, the body treats these as poisons and attempts to eliminate them as rapidly as possible. Those substances which cannot be eliminated through regular channels of elimination are stored in the tissues and accumulate there. This forms the basis of a toxemic state. When toxins accumulate to a certain extent the body makes a concerted effort to rid itself of this unwanted debris. Thus, we witness signs of acute disease. It may be in the form of a cold, bronchitis, flu, skin eruptions, diarrhea, etc. If at that point symptoms are suppressed, we have the basis for chronic degenerative disease.

## **Eliminative Causes**

In order to eliminate disease we must first eliminate the cause of disease. If you are consuming junk food, this practice must be stopped if health is to be regained. By junk food we mean foods that have been so altered and impaired in the process of manufacturing, bleaching, canning, cooking, preserving, pickling, etc., that they are no longer as well fitted to meet the needs of the body as they were in the state Nature prepared them.

We do not need junk foods. We can delight in the exquisite flavors of all the fresh fruits which are so easily available now. These foods need no altering or refining to make them truly appealing.

A diet of fresh fruits, vegetables, nuts and seeds is one which will result in true health and vigor. Eliminate junk foods and your body will respond favorably.

[Home](#) > [Lesson 35 - Junk Foods: A Case Study On Molasses](#) > Article #3: Food In Your Poison by Viktoras H. Kulvinskis

### **Article #3: Food In Your Poison by Viktoras H. Kulvinskis**

Although Americans are eating more, (in spite of high food prices), they are receiving less nourishment. Real food, for the most part, is virtually unknown. Most Americans don't care. Their attachment to food is emotional and induced by advertisement. They load their shopping carts with a variety of colorful, unnutritious, plastic foods, saturated with synthetic ingredients. "Oh! But it tastes so good," they exclaim as they endlessly cram their stomachs, but remain unsatisfied.

More and more people are becoming conscious that both shelved and perishable products in the supermarkets do contain a wide array of poisons. The mass media, even as they glorify such products, announce that they are embalmed with over 3,000 questionable chemicals.

The average consumer as defined by scientific literature and popular publications is a phenomenon of the 20th century, with no antecedent in history. There was a time when no one dined on poisons and called it lunch. Food producers are deliberately supplementing the diet with food additives of a toxic nature at the rate of over three pounds per year for every person in America.

A stranger in our land, reading labels, might wonder whether American food is too "fresh." Almost every package has something added to preserve "freshness": BHT, sodium propionate and a host of other preservatives. After a "fresh" imitation dinner, a dizzy spell, difficulty in breathing, or a peculiar feeling in the stomach is very common. Some even think it is love when the pulse rate increases and they become feverish. Others turn to the "imitation life box" for relief from their distress. Every other commercial, served at the rate of 60 doses per hour, encourages food habits that lead to disease or

prescribes a potion to alleviate food-induced illness. They lull us into the belief that it is all right to sin as long as we turn to the right product for forgiveness.

Most shoppers in 1970 anticipated the removal of cyclamates from the market. They may instead discover that the fine print on the label warns that the additive may be dangerous to one's health. Yet this chemical is capable of inducing cancer, and recent tests show that calcium and sodium cyclamate can induce chromosome breakage in the human leucocyte in vitro and in rat spermatogonial cells in vivo. Its effects are very similar to a type of chromosome damage reported for LSD as well as caffeine when used in large doses.

An article headlined: "Are Cancerous Chickens Edible?" Yes! People will eat anything. "If tumors are detected on the wing of a bird, the wing could be cut off and used in products like hot dogs and the rest of the bird sold as cut-up chicken—all supposedly without posing a threat to human health."

It is well known to chemists that subjecting organic compounds to high temperatures produces complex polycyclic compounds by pyrolysis. Several carcinogens are included in this group of compounds. A benzopyrene (carcinogenic) content, as high as 50 micrograms per kg was found in some instances. It seems to arise from pyrolysis of fat when cooking food. The amount produced increases with increased fat content and longer and closer exposure of the food to the flame. Benzopyrene is found also in all smoked foods. The relatively higher incidence of gastric cancer in Northern Russia and Iceland has been related to the large quantity of smoked fish eaten by the inhabitants of these regions. In a review of cancer-causing properties of benzopyrene, it was found to be quite high in salami, salmon, bacon and provola.

Eating heated fats may be deadly. Animals fed cooked fat die prematurely said Dr. R. Kurkella, University of Helsinki. Research has discovered that the more fat a person eats, the shorter will be the life span.

Meat, the most perishable (and most expensive) of all foods is also one of the most tampered with. To see exactly how meat is produced one should read the Animal Machine by Ruth Harrison. It is the story of animal factories, where animals may live out their lives in darkness, immobile in steaming pens from birth to death, fed by conveyers containing drugs, antibiotics, tranquilizers, pesticides and hormones.

After an animal is slaughtered, or dies from disease, it is shipped off to the processing house. The meat is doctored up, for the benefit of the gullible public, with aesthetic beautifiers, stink reducers, taste accentuators, color additives, drug camouflagers, nutritive "enhancers," bleaching agents and death certificate. No corpse gets such a face lift by the embalmers and with good reason, for the corpse is soon buried, whereas salami, hotdogs, bologna, and chicken may sit on the shelves for months.

Meat is colored red with sodium nicotinate, otherwise it would turn yellow-gray. Uneven or excessive application can result in severe sickness, even death. However, when such incidents occur, they are seldom diagnosed correctly. At the Congressional Hearing on Meat Inspection it was reported that the sausages, ham, hamburgers, and the hot dogs you eat may be filled with hog blood, cereals, lungs, niacin, water, detergents and/or sodium sulfide.

The FDA refuses to recognize tests conducted by Dr. Patrick Riley at a London Medical School, where it was shown that BHA, a widely used preservative, is carcinogenic.

This preservative appears in luncheon meats, such as salami, bologna, and pressed ham, canned meats, peanut butter, canned chicken and other foods. Senator Alan Cranston commented in 1970 that "perhaps they (FDA) consider food processors' interests more than people's interests."

A typical associated press release occurred around Thanksgiving 1969: "U.S. finds pesticide in 90,000 turkeys in toxic levels." A few years ago cranberries were found to be unfit companions to the turkey. In Massachusetts alone during a more active month for health inspectors, 250 tons of meat were seized because it was contaminated. Such meat is quite often resold as 4-D meat: dead, dying, disabled or diseased. The winter of 1969, Boston had a month long scandal over the pollution of the slaughter

houses of Massachusetts. Someday we are going to be civilized enough to be concerned over the killing and torture that goes on in the same slaughter houses.

ONLY TEN PERCENT of the meat adulterated with pesticides and chemicals, or contaminated with filth and diseased organs is condemned by food inspectors. The other 90 percent gets through to the unsuspecting consumer, so claims Leray Houser of the Health Education and Welfare Department.

"In 1965, a total of 711 firms suspected of producing harmful or contaminated consumer products refused to let the FDA conduct inspection...the FDA does not have subpoena authority either to summon witnesses, or authority to require firms to divulge pertinent records."

A very striking observation about the quality of animal products comes from the lips of the Health, Education and Welfare Secretary, Robert H. Finch, who FEARED THAT WE WOULD BECOME "A NATION OF VEGETARIANS" if there were strict enforcement of pesticide residues in red meat, dairy produce, eggs, fowl and fish.

Today we are faced with an external environmental crisis. We can control the inner body environment through good diet, pure water and joyful, positive thoughts. To procure good organic food economically, cooperation is a must.

## Lesson 36 - Junk Foods: A Case Study Of Garlic And Onions

- [1. Introduction](#)
- [2. History of Garlic](#)
- [3. The Garlic Plant](#)
- [4. Claimed Health Benefits](#)
- [5. Onions](#)
- [6. Claims Of Health Benefits](#)
- [7. Are Onions And Garlic A Food?](#)
- [8. Questions & Answers](#)
- [Article #1: Are Garlic and Onions Helpful in Preventing Stroke?](#)
- [Article #2: Gorgeous, Glorious Garlic](#)

### 1. Introduction

Even though garlic or onions are not processed or altered, they are regarded as junk foods because they do not contribute to the welfare of the body when ingested. On the contrary, they contribute to disease by adding toxins to the body. As you will learn from this lesson, there are no health benefits to reap from ingesting either of these foods. They both contain toxic irritants which result in much harm when included in the diet and should, therefore, never be consumed. The importance of this statement will become evident upon completion of this lesson.

### 2. History of Garlic

Garlic is a hardy perennial bulb, native to the Mediterranean region of Africa and Europe. Its history dates back many centuries, and it was long used for rubbing the newborn infant's lips, and as a protection against disease by tying it around the throat.

The sun, the Cross, and garlic are the only three things reputed to scare away vampires. Both the ancient Egyptians and Greeks regarded garlic as having supernatural powers.

During the 17th century, garlic was credited with protecting many European households from the ravages of the Great Plague. In New England during Colonial times, garlic cloves were bound to the feet of smallpox victims. Cloves were also placed in the shoes of whooping cough sufferers. For intestinal worms, raw garlic juice or milk which had been boiled with garlic was often drunk. A clove or two of garlic pounded with honey and taken two or three nights successively, is good for rheumatism, herbalist lore tells us.

During World War I, garlic was used as an antiseptic in hospitals. Pads of sphagnum moss were sterilized, saturated with water-diluted garlic juice, wrapped in thin cotton, and applied as bandages to open wounds.

### 3. The Garlic Plant

The botanical name for garlic is *Allium sativum*. This hardy bulbous plant is a member of the lily family, which also includes leeks, chives, onions, and shallots. Like the onion, the edible bulb of the plant grows beneath the ground. This compound bulb is made up of several small sections or bulblets called "cloves" which are encased in thin papery envelopes. The cloves are eaten and also used for planting. Farmers plant the crop in early spring and the bulbs mature early in the fall. The bulbs are "cured" by drying in the field. Workers then braid the tops or remove them, and the garlic is ready for market. The bulbs are either sold whole or ground into powder. The juice of the garlic bulbs may also be extracted and sold.

#### 3.1 Garlic's Pungent Flavor

Garlic is most often used to season foods because of its pungent flavor. A substance in garlic, called allicin, is responsible for its flavor and odor.

#### 3.2 An Antibacterial Agent

Allicin is an antibacterial agent and an extremely irritating liquid. It has a drug-like property which, like any other drug, destroys life. Antibacterial agents kill bacteria. Do we wish to kill bacteria? Certainly not! Bacteria are essential components to life and without them life would not continue.

As students of Life Science, you know that bacteria do not produce disease but perform a very important function. These useful organisms come into action when the cell has finished its life cycle to decompose the dead cell and help to eliminate it from the body. They also act to clean up toxic material which the body eliminates. This is why they are often seen during a disease process.

Bacterial action takes place in all disease phenomena because these are processes requiring the breaking down or disintegration of accumulated refuse and toxic matter within the body, which the system is endeavoring to throw off. But to assume, as many medical scientists do, that merely because the bacteria are present and active in all disease phenomena, that they are therefore the cause of these same diseases, is just as wrong as it would be to assume that because bacteria are present and active in the decomposition process connected with all dead organic matter, they are the cause of the death of the organic matter in question. Bacteria are part of the results of the disease, not its cause.

It does not make sense to ingest a food which would interfere with or destroy this important function within our body.

#### 3.3 An Anthelmintic and Rubefacient

According to Stedman's Medical Dictionary, the volatile oil from the bulb or entire plant of garlic is used as an anthelmintic and rubefacient. These are big words, but with big effects. We will take them one at a time.

An anthelmintic is an agent that destroys or expels intestinal worms. Now if one suspects that he or she has intestinal worms, one had better look very closely at his or her diet and lifestyle. And then run (don't walk) to their nearest Hygienic practitioner and go on a long fast! Taking an anthelmintic drug would not be the answer in any case as we cannot promote health by ingesting deadly poisons.

Any agent which is so poisonous as to cause immediate death to any other living organism should *never* be consumed. If this volatile oil, which is part of the garlic plant, is so powerful as to result in death of internal parasites and bacteria does it not stand to reason that it would also have a serious detrimental effect on the entire organism?

When any food is ingested, it goes through the same process of digestion and assimilation. Its components are broken down, absorbed through the intestinal lumen and eventually find their way into the bloodstream and lymph. These components are then carried throughout the body and the nutrients are used by the cells as needed. Nonusable components are, of course, rejected and eliminated. If these components are deadly poisons, much harm can be done as they circulate throughout the system and possibly combine with other chemicals within the body or are stored in the tissues.

A rubefacient is an agent which results in reddening of the skin. In other words, as soon as the extracted oil from the garlic is applied to the skin, a redness will result. What does this mean? Redness indicates inflammation and the body's response to an irritating substance. The body attempts to isolate this invading substance so that it does not enter the bloodstream and create further problems for the body to deal with.

We may assume that if this reaction occurs when this oil is applied topically, extreme irritation must result when it comes in contact with the more delicate lining of the gastrointestinal tract.

We know that the body regards garlic as a poison and attempts to eliminate it as soon as possible. Anyone knows that when they ingest garlic (even a very minute quantity) the odor will remain on the breath and even the skin will smell of garlic. The body is eliminating this poison through the lungs and skin, which seem to be the most rapid and efficient routes.

[Home](#) > [Lesson 36 - Junk Foods: A Case Study Of Garlic And Onions](#) > 4. Claimed Health Benefits

## **4. Claimed Health Benefits**

Many authors claim that garlic is a "miracle food" and recommend it to 'cure' all types of ailments. Paavo Airola says, "garlic is, indeed, a tremendously nutritious health food and a miraculous healing plant. It can truthfully be called 'the king of the vegetable kingdom.'" In the book, *Herbal Medicine*, Dian Dincin Buchman says, "If garlic weren't so cheap, we would treasure it as if it were pure gold. Garlic draws out pain, helps in resisting a cold, is an aid in combating hypertension, is a remarkable vermifuge (releases worms from the system), quiets the body, tranquilizes, can be directly applied to warts to whittle them down, can be used (diluted in lots of water) to irrigate the colon to control amoebic dysentery, and can help treat mild cases of mononucleosis."

In other words, garlic is a powerful drug which results in the suppression of symptoms. But causes have not been removed and no healing has occurred. We have, in fact, halted the healing process when we suppress the symptoms.

### **4.1 Reduced Blood Pressure**

Paavo Airola says that, "In my own clinical practice, I have treated many patients with high blood pressure; in most cases the blood pressure was reduced 20-30 mm. in one week by taking large amounts of garlic and garlic preparations."

This was a very dramatic drop in the blood pressure of this patient. What would cause this pressure to drop so quickly? Was it the 'miracle' preparation of garlic? No, garlic has no ability to act just as no drug has the property to act upon the body. But the body does respond to food and toxins which enter. Furthermore, the garlic does not have a mind of its own to treat specific symptoms. It goes through the same digestive process as other foods and enters the circulation. The body detects it as a poison and marshals all of its forces to deal with that poison. Meanwhile, other bodily functions are slowed or depressed while this energy is being directed toward the emergency at hand. If there were healing in the

heart, the body would have to stop this process in order to deal with the poison. Continued consumption of large amounts of garlic would have a continued depressing effect on the heart and all the bodily organs and a state of enervation or exhaustion would occur. It may be especially enervating on the heart as opposed to another organ in persons who have high blood pressure because this may be their weakest organ. One should not palliate symptoms but remove the cause of disease.

## **4.2 Prevents Plaque Formation In Arteries**

It is claimed that garlic prevents the formation of plaque in the arteries and thus helps prevent the development of arteriosclerosis and heart disease. Paavo Airola describes one experiment where one-fourth pound of butter at one time was given to five healthy volunteers. Three hours after the volunteers had eaten the butter, their cholesterol levels had risen from an average of 221.4 to 237.4. Later, the same volunteers received the same amount of butter along with the juice of 50 grams of garlic. This time, the cholesterol levels, instead of rising, went down from 228.7 to 212.7 in three hours. Now that really was a "miracle," or was it?

Now we must recognize that no one consumes one-fourth pound of butter in one sitting. The cholesterol levels in the blood would naturally rise after such a meal. But this is where the cholesterol should be after the meal—in the blood. Excess is then eliminated (as much as possible). That is, under ordinary circumstances, the excess would be eliminated when the body is not so drastically overloaded.

When the volunteers were given garlic with the butter, blood cholesterol levels were reduced. Where did the fat go? Did it disappear? No, it is still in the body, but it is in the tissues and has not remained in the blood. Allicin makes the cells and tissues more permeable and substances enter which would not ordinarily enter.

Garlic also interferes with certain physiological processes. It is known to interfere with the synthesis or breakdown of lipids in the liver. This is why the cholesterol level of those ingesting garlic over a period of time is lower. However, the body synthesizes cholesterol in the liver for a reason and it is needed for certain cellular functions. Any agent which interferes with any normal bodily function is health-destroying and not health-promoting.

The body has its own way of controlling the amount of cholesterol which is in the plasma. Cholesterol synthesis, as well as the hepatic mechanism for removing this steroid from the plasma, are both stimulated by thyroxine. Thyroxine is the hormone which is produced by the thyroid gland. This hormone plays a role in many metabolic activities besides control of cholesterol in the plasma as will be explained later. The output of thyroxine is controlled directly by thyroid stimulating hormone (TSH) secreted by the anterior pituitary. These mechanisms are part of the body's homeostatic mechanisms of checks and balances to keep all bodily actions and reactions in harmony and in balance.

A substance which is present in garlic as well as onions is mustard oil. Mustard oil is metabolically converted to thiocyanate in the body. This substance contributes to the formation of goiter by decreasing thyroxine synthesis in the thyroid gland. Thus, when garlic is eaten, thyroxine is decreased and therefore cholesterol synthesis is reduced.

Garlic then results in the interference of a very important homeostatic mechanism. The impairment of this mechanism does not have just one effect but many. Remember, the body works as a unit and never as separate independent parts.

People think that they have discovered a wonder drug or a miracle food just because one symptom has vanished—in this case, elevated serum cholesterol. In reality, it is a grave deception—an illusion.

Quite often one hears that excessive lipids are the major causes of heart disease. This is not quite the truth. The real cause is the overloading of toxins created through the over-consumption of fats in the diet and in general, an unnatural diet.

### **4.3 Garlic Cures Anemia**

It has been claimed that garlic extract has a beneficial effect in the treatment of anemia. This is far from being the truth. In fact, the use of garlic actually results in anemia. The red blood cells are actually destroyed by the allicin in garlic.

### **4.4 A Cure For Arthritis**

It has been claimed that garlic exhibits some anti-inflammatory activity and is therefore effective in the treatment of arthritis.

One cannot get well by suppressing disease. We must remove the cause of disease and provide the conditions for health. Then the body will heal. Garlic undoubtedly does have some anti-inflammatory drug effects. However, this is not a good aspect but an adverse one. Inflammation should never be suppressed as it is a healing response without which even a mild infection could become fatal. To suppress this response by an anti-inflammatory agent is to suppress healing. To more fully understand the consequences of suppressing inflammation, we will take a closer look at this process.

### **4.5 Inflammation**

As mentioned, inflammation is a healing response within the body. Whenever there is tissue damage as a result of disease or injury, the damaged tissue cells produce histamines. These histamines cause changes in tiny blood vessels, which in turn release fluids into the injured area. Local blood flow increases, bringing blood cells whose specialty is destroying foreign microbes to the area. Along with these disease-preventing cells comes fibrinogen, which causes clotting. The clotting results in what is called "walling off," that is, Nature literally builds a partition between the infected area and the rest of your body. The effect is to prevent the infection from spreading. This partition, or wall, stops body fluids from moving outside the infected area, and these fluids build up in the area, causing the characteristic swelling of inflammation.

Before inflammation can arise, there must exist an exciting cause in the form of some obstruction or of some agent inimical to health and life. In this light, we see inflammation as a healing process.

The body does not suppress the growth and multiplication of disease germs until the morbid matter (toxins) on which they subsist has been decomposed and consumed, and until the inflammatory processes have run their course. The use of serums, antitoxins or anti-inflammatory agents given to suppress germ activity and the process of inflammation before it has run its natural course will lay the foundation for chronic destructive disease.

### **4.6 Garlic—A Body Detoxifier**

How could any agent which is so poisonous and irritating be a detoxifier? It does, in fact, add toxins to the body. It is claimed that it detoxifies by stimulating the liver, the nervous system and the circulation. This stimulating effect is in reality the body's response to an unwanted agent and the body's efforts to eliminate it as quickly as possible. The ingestion of this food as a stimulant will, according to the Law of Duel Effects, eventually depress these organs. Only much harm can come from this practice.

### **4.7 An Anticoagulant Agent**

One of the so-called benefits of garlic is claimed to be its anti-coagulant factor. In other words, it inhibits blood clot formation. In truth, this is not a benefit but an undesirable factor. As we all know, if our blood did not clot, we would bleed to death from a slight wound.

In certain disease conditions, a thrombosis (blood clot) occurs in the blood vessels. But if given the proper conditions, the body is equipped to handle this also. Nature has its own anticlotting factors.

Heparin occurs naturally in the body tissues. It reduces the ability of blood to clot by blocking the change of prothrombin to thrombin. Thrombin is the enzyme responsible for the formation of fibrin which is the structural ingredient in blood clots.

If a blood clot occurs with a blood vessel, a system within the body called the fibrinolytic system digests the fibrin clots into a number of soluble fragments.

## **4.8 Pesticidal Properties**

The following are just some of the pesticidal properties of garlic:

1. Causes 100% mortality in 5 species of mosquito larvae when used in such small doses as 200 parts per million.
2. Planting rows of garlic plants between rows of vegetables or flowers which are specifically vulnerable to insect attack, such as rose, tomatoes, potatoes, cabbage, etc. will prevent insect infestations and protect plants.
3. When used on dogs, garlic will kill ticks within 20-30 minutes.

Would you put a pesticide on your salad? We had better leave the garlic in the garden!

[Home](#) > [Lesson 36 - Junk Foods: A Case Study Of Garlic And Onions](#) > 5. Onions

## **5. Onions**

The onion is one of the oldest vegetables known to man, having been cultivated from the most remote period, as references in Sanskrit and Hebrew literature indicate. It is represented on Egyptian monuments. An inscription on the Great Pyramid states that sixteen hundred talents had been paid for onions for the workmen who built the Pyramids. There were certain religious sects who maintained that onions were impure and forbade their disciples and priests to eat them.

### **5.1 The Plants**

Onions were raised in America as early as 1750. The leading onion-growing states include California, Idaho, Michigan, New York, Oregon and Texas. But onions are grown in many other states and Canadian provinces. Mexico, Italy, and Spain are also noted for their onions.

The onion plant is a biennial (a plant that lives for two years). The upper part of the plant is a set of leaves growing inside each other. The lower part of the leaves become very thick. The flowers are small and white, and grow in round clusters. The bulbs are enclosed in a thin papery covering made up of dried outer leaves. The onion plant has a few shallow roots.

The different kinds of onions have many sizes, colors, and shapes. People who trade in onions classify them as American (strong onions) and foreign (mild onions). The strong type includes the Yellow Globe types and the flatter Ebenezer type.

The onion is not particularly high in vitamins or in energy value.

### **5.2 A Toxic Substance**

The substance in onions which gives them their characteristic odor and flavor is mustard oil, a volatile oil which is highly toxic. Its vapors are so irritating that they cause profuse watering of the eyes just by being in contact with the vapors for a few seconds. This oil, if applied directly to the skin, would cause

extreme redness and blistering.

Anyone can testify to the fact that after they have eaten onions, even if it was only a small amount, the onion smell stays in their breath for a long time afterwards. The body eliminates much of this toxic oil through the breath as it attempts to get rid of this poison from the system.

### **5.3 Contributes to Goiter**

As mentioned earlier, the mustard oil is metabolized in the body to thiocyanate. Ordinarily small amounts of thiocyanate are eliminated. But in large amounts this substance is highly toxic and results in disease. Thiocyanates are goitogenic. They contribute to the formation of a goiter by decreasing thyroxine synthesis in the thyroid gland. Thyroxine performs many important functions in the body.

One important function that thyroxine has in the body is to increase the rate at which cells burn their fuel, glucose. It also works in partnership with cortisol (a hormone of the adrenal glands) in defending the body against stress resulting from extreme cold. Thyroxine is also involved in other antistress responses. Emotional stress and severe hunger also provide an elevated thyroxine output. In general, thyroxine comes into play when there is an extra demand for energy. Thyroxine also increases the heart rate. When it is synthesized within the cells of the thyroid, this hormone becomes a part of a protein (thyro-globulin) until needed. When needed, a complex reaction involving the proteolysis (hydrolysis) of thyroglobulin and the synthesis of thyroxine takes place.

This is the point where the thiocyanate interferes with the synthesis of thyroxine. Apparently, the interference occurs with this protein but further research still has to be done in this area. At any rate, much harm can result.

### **5.4 Onions and Anemia**

In *The Complete Book of Food and Nutrition*, J.I. Rodale relates a series of experiments concerning the adverse effects of eating onions. According to Rodale, Dr. M. Kaiser, of the University of Illinois College of Medicine, gorged (experimentally) on enough onions to bring himself down with an all-out case of anemia in a single week.

Experimenting with dogs, the same Illinois scientist first tried them out on the ordinary onion oil extract that is widely used in restaurants and homes for food-flavoring, and discovered that a daily dose of a mere quarter teaspoonful of this substance produced the disease in marked degree. Found to be too potent to try in a proportionate scale on humans, this extract should, they agreed, not even be used in extreme moderation in seasoning.

The next stage in the course of their study consisted simply of enlisting volunteer medical students to overeat the plain food, and in this stage Dr. Kaiser himself participated. Besides their regular diet, the group consumed over two pounds of cooked onions daily for 5 days. At the end of this time all showed typical anemia symptoms, dragging themselves around in an exhausted state and turning pale to their fingertips. On laboratory examination, the red cell count in their blood exhibited a drop of about a million, and the hemoglobin content was also starkly reduced. But this was only a slight anemia when compared with that of the dogs, which for 15 days had been fed comparable amounts of the pungent bulbs. In the animals both red cell count and hemoglobin had sunk to 50 percent below normal.

This destruction of the red blood cells and subsequent liberation and loss of hemoglobin has very grave consequences to the body's overall integrity. The red blood cells, along with the other constituents of the blood, perform many very important functions. Below is a list of just some of these duties:

1. It is the medium by which oxygen is transported from the lungs to the tissues.
2. Carbon Dioxide, a product of the metabolism of cells is transported from the tissues to the lungs.
3. Nutrient materials are absorbed from the intestine and carried to the tissues.
4. Many organic substances that represent breakdown products of metabolism are carried by the

blood to the kidneys for excretion.

5. Hormones, the secretions of ductless or endocrine glands, are distributed throughout the body by the bloodstream.
6. The blood flows from the deeper and warmer parts of the body to the extremities and tends to distribute heat more evenly to all parts of the body.
7. The blood plays an important part in maintaining acid-base balance of the tissues.
8. There is a constant relationship between blood volume and the fluid content of the tissues.
9. The ability of the blood to form a clot and so reduce bleeding has been of survival value to animals and man.
10. The blood performs an important part in cleaning up foreign matter and dead cells from the body.

We can thus see that by disturbing one thing in the body we disturb many functions. But these problems can be avoided simply by staying on a correct diet and avoiding such toxic foods as garlic and onions.

[Home](#) > [Lesson 36 - Junk Foods: A Case Study Of Garlic And Onions](#) > 6. Claims Of Health Benefits

## 6. Claims Of Health Benefits

It has been claimed that onions 'cure' coughs, colds, flu, sinus ailments, bruises, hemorrhoids, and chilblains plus assorted other diseases.

As Hygienists, we know that this could not be true. Only the body can heal. The use of onions may suppress disease symptoms but this is certainly an undesirable effect as this results in suppressing our body's attempts to heal.

Poisons do not heal—poisons only poison. There are no health benefits in eating onions.

[Home](#) > [Lesson 36 - Junk Foods: A Case Study Of Garlic And Onions](#) > 7. Are Onions And Garlic A Food?

## 7. Are Onions And Garlic A Food?

In order for a food to be considered an acceptable part of our diet it must not contain harmful or toxic substances. It must not furnish the body with digestive and eliminative problems. Neither garlic nor onions qualify in this respect.

The food must be delicious. We should be able to eat it with relish. We can't really say we relish the strong flavors of garlic or onions. Just peeling onions is a job most people dread!

The food must be easy of digestion and assimilation. Does not qualify here!

The food must contain a rather broad range of nutrients and be fairly complete in their complements of nutrients. Both onions and garlic offer little food value.

We should be able to make a mono meal of the food if we desire. No one could make a complete mono meal of either garlic or onions or even consider doing so. Whereas, a mono meal of watermelon, mangoes, grapes, peaches, cherries, or oranges is very appealing.

The conclusion is undeniable that neither garlic nor onions is a true food and they both should be

excluded from our diet. I cannot really imagine that anyone would greatly miss these items as they are not really appealing and their after-effects (such as bad breath) are so disturbing. Do yourself a favor and eliminate garlic and onions and you will reap the benefits by increased health and vigor.

[Home](#) > [Lesson 36 - Junk Foods: A Case Study Of Garlic And Onions](#) > 8. Questions & Answers

## **8. Questions & Answers**

### **Would onions be all right to eat if they were cooked?**

Since mustard oil in the onions is a volatile substance, some of it will evaporate during the cooking process. However, enough will remain to make it a toxic substance. Furthermore, I do not recommend cooking as it alters or destroys most food constituents and contributes to toxins in the body. Try staying with an all raw food program and you will find that you will not require onions for seasoning.

### **I always heard that if you wear a clove of garlic on a string around your neck during the winter, it wards off colds. Any truth to this?**

No, it is just an 'old wives tale' which has been passed down through the generations.

### **Are the milder tasting onions less harmful than the stronger ones?**

They are somewhat better but still contain enough mustard oil to warrant keeping them off the diet.

### **Why do I always experience indigestion following a meal that contains either garlic or onions?**

All members of the onion family—onions, garlic, leeks, shallots, chives, etc.—as well as radishes and all other foods containing appreciable amounts of mustard oil—inhibit digestion. This is because they occasion irritation of the stomach and intestines.

[Home](#) > [Lesson 36 - Junk Foods: A Case Study Of Garlic And Onions](#) > Article #1: Are Garlic and Onions Helpful in Preventing Stroke?

## **Article #1: Are Garlic and Onions Helpful in Preventing Stroke?**

A reader of the Health Crusader has submitted an article praising onions and garlic as useful in preventing stroke. He was sure we were right in our stand on garlic and onions but is not so sure now that he read the article that says we need these obnoxious plants to prevent stroke.

The article says "these smelly vegetables are beneficial in treating many ailments." Now two scientists (unnamed in the article) have isolated the compounds (also unnamed) in garlic and onions which prevent the clumping together (clotting) of blood cells that block circulation and cause strokes.

Of course we know the names of these substances in onions and garlic. They are allixin, a poison on the same order as digitalis (an extract from foxglove) and mustard oil, a highly volatile oil that goes through

cell membranes and gets into the cells with great ease. The body cannot digest either of these poisons nor make use of them. They go into the tissues and blood quite readily and cause havoc. The body violently objects to poisons and the eliminative and purifying organs are burdened with a big job. The kidneys, lungs and liver become injured. Their ability to get rid of poisons becomes impaired as they are abused and overworked.

In this article is a basic mistake, namely, the presumption that strokes must be prevented. Nothing is further from the truth. They must be caused! We must not consume disease-causing, sickness-promoting "foods" and drugs. We need to obtain plenty of rest, exercise, and fresh air. Healthy people don't get blood clots, and taking substances of any kind which contain poisons will not make up for wrong living and eating habits. It will only add to the body toxicity that caused the problems in the first place.

Let's not eat overly strong foods containing poisonous substances in the mistaken belief that we can prevent stroke or any other health problem. That which is not bound to happen doesn't have to be prevented or avoided. Vibrant health is normal and will exist unless disease is caused.

[Home](#) > [Lesson 36 - Junk Foods: A Case Study Of Garlic And Onions](#) > Article #2: Gorgeous, Glorious Garlic

## **Article #2: Gorgeous, Glorious Garlic**

Beauty is in the eyes of the beholder. To us, a ripe red apple entices. To a tiger, a gory red carcass is enticing.

So, in seeing an article that sings the praises of garlic in the November, 1978 issue of Reader's Digest, I wonder what is at the heart of it. Magazines usually don't devote their space to something without a commercial angle unless there is an overriding reader interest. But let's presume this article is simply an effort to present a topic of general interest which they sincerely feel will benefit their readers.

When we get into the article we find that garlic is praised for about everything except its food value. In fact the windup is that garlic is a "flavoring agent," a condiment. But in between we find it is quite toxic (not by the tenor of the article but by some of its uses as an antibiotic and an insecticide). It was noted that its juice can be used as an antibiotic to kill a culture of bacteria in just minutes.

We organic gardeners have long known that we can protect our gardens well by planting garlic amongst some of the rows. Also, it is suggested that the juice of garlic can be used for killing mosquito larvae, aphids, houseflies, caterpillars, etc.

But we of life Science recommend that you not eat garlic because of its poisonous qualities. To be sure, the mustard oil of garlic is the sole ingredient for which it is recommended. And just as surely, it is a poisonous indigestible oil that plays havoc with the human constitution just as does the capsicum of hot peppers, the nicotine of tobacco, the solanine of the nightshade family or any of the myriad of other poisons of popularity referred to as herbs.

There will be a day when garlic and other plants bearing poisons will be recognized for what they are and shunned rather than praised.

## **Lesson 37 - Fermented And Putrefied Foods In The Diet; Studies Of Other Junk Foods**

- [1. Introduction](#)
- [2. The Myths Of Fermented Foods](#)
- [3. The Harmful Effects of Fermented Foods](#)
- [4. Types of Fermented Foods in the Diet](#)
- [5. Questions & Answers](#)
- [Article #1: Excerpt from The Health Crusader](#)

[Home](#) > [Lesson 37 - Fermented And Putrefied Foods In The Diet; Studies Of Other Junk Foods](#) > 1. Introduction

### **1. Introduction**

RECIPE: "Take one fish and press it under a heavy stone for 24 hours. Remove the fish and pound it until soft and add two cups of salt. Lay the fish in the open sun for another day. Pack fish into straw and put into an open jar. Set jar with fish out in the sun for another month. Smash month-old salted fish into a paste and use it as a soup or spread. Delicious!"

This is a recipe for probably the first fermented food ever eaten by man. Today he eats many more types of foods that have undergone some fermenting processes. Cheese, yogurt, pickles, sauerkraut, soy sauce, vinegar, beer and buttermilk are some of the more common fermented foods eaten today.

None of them are necessary in the diet.

#### **1.1 What Is A Fermented Food?**

A fermented food is basically a food that has been very carefully spoiled. Fermentation occurs when certain microorganisms (bacteria) break down a food into various waste products. If the "wrong" types of microorganisms decompose the food, then putrefaction, or rotting, occurs.

Fermented foods, then, are the result of active bacteria and contain their waste products (lactic acid and acetic acid are two examples). Putrefied or rotten foods also contain bacteria and certain waste products (usually a nitrogenous substance like ammonia).

Why do people want to eat rotting or decayed foods? Can these foods be beneficial in any way, as some people have claimed? What happens when you eat fermented foods?

#### **1.2 How Fermented Foods Began**

Fermented foods like yogurt, pickles, beer and so on were originally used as a substance for fresh foods. Fermentation became a way of preserving foods for the time when there was no supply of fresh food. In effect, man found a way to "spoil" his food by choice so that he could eat it at a later date.

Cheese, for example, was one way that milk could be preserved without refrigeration. Excess cucumbers and cabbage were turned into pickles and sauerkraut for the winter. Fermented foods were actually some of the first preserved foods.

And, like all preserved foods, they cannot supply the ingredients of good nutrition. Still, man has eaten them for hundreds of years, and over that time he has developed some good reasons (or excuses) for

eating foods that are full of bacteria, decay and waste products. Let's look at the reasons given for including fermented foods in the diet.

[Home](#) > [Lesson 37 - Fermented And Putrefied Foods In The Diet; Studies Of Other Junk Foods](#) > 2. The Myths Of Fermented Foods

## 2. The Myths Of Fermented Foods

Fermented foods have been used and have been recommended in the diet for basically four reasons:

1. Fermented foods are a healthy way to preserve food.
2. Fermented foods can replace beneficial bacteria in the intestines.
3. Fermented foods can aid digestion.
4. Fermented foods are necessary for a long life. All of these reasons are false.

### 2.1 Fermentation Is NOT A Healthy Way To Keep Foods

Once a food has begun to ferment, it usually continues to do so until it has completely rotted. To halt the fermentation process, either salt, vinegar or extreme cold is used to inhibit the growth of the bacteria living in the food.

Many fermented foods are heavily salted. Salt is a biocide. It kills and inhibits life. The salt in fermented foods prevents the native bacteria from multiplying to the point where putrefaction occurs.

Salt is a useless and harmful inorganic chemical that should never be eaten. Pickles, sauerkraut, cheese and other fermented foods are very heavily salted. Foods preserved with salt should not be included in the diet.

Vinegar is another popular additive to various fermented foods. Vinegar itself is the result of fermentation and is used in concentration to halt the continual decay of fermented foods.

Vinegar, however, disrupts the digestion, kills healthy blood cells, and irritates all the membranes. Pickles and other foods which have been soaked in vinegar are rendered totally indigestible. Many times the digestive juices cannot penetrate and break down the food preserved by vinegar, and so the fermented food passes through the system just as it was swallowed.

A few fermented foods, such as yogurt and beer, are not salted or preserved with vinegar. These types of fermented foods are usually held at low temperatures or bottled to inhibit the continuing growth of the fermenting bacteria ?

### 2.2 Fermented Foods Do NOT Replace Beneficial Bacteria

One of the reasons most often given for eating fermented food is that they replace beneficial bacteria which naturally live in the intestines. These bacteria aid in the breakdown of food particles and are a part of our native intestinal microflora.

By eating foods rich in bacteria (such as fermented foods), it is believed that our own native bacteria will be enriched and re-established. It sounds reasonable, but this is also a myth.

The effects of fermented foods on the intestinal bacteria are only transitory at best. For example, one of the major so-called beneficial bacteria is called *Lactobacillus bulgaricus*. It's found in yogurt and other naturally fermented foods.

This bacteria, however, *is not a normal inhabitant of the intestine*, and it does not survive long in that environment. In fact, as soon as the foods containing this bacteria are no longer eaten, this "beneficial" bacteria packs its bags and leaves your intestines with the next bowel movement.

Still, there is the persistent insistence that fermented foods can somehow re-establish the needed bacteria in the intestines. People are often advised to drink buttermilk or eat some yogurt or take a swig of acidophilus after taking antibiotics which have killed the "beneficial" bacteria along with the so-called "harmful" bacteria.

This is quite humorous. First, some bacteria are deemed bad or harmful and a pill is taken to kill them. But the pill works too well, and bacteria we call "good" are also killed. So now we must eat foods full of bacteria to get the "good" bacteria back into our system!

Because of these claims made for fermented foods, much research has been done to see if they can indeed reestablish beneficial bacteria in the intestines. According to a study reported in the *American Journal of Clinical Nutrition*, the influence of "dietary microflora (bacteria) on the large intestine microflora is unsubstantiated." The researchers also discovered that even eating *two pounds daily* of true Bulgarian yogurt "failed to elicit a response in the fecal flora."

### **2.3 Myth: Fermented Foods Aid Digestion**

When a rotten or spoiled food is eaten, the body hurries it to the nearest exit in an effort to protect itself. If the food is extremely putrefactive, diarrhea may result. If the food is fermented, an increased motility of the intestines occurs. This increase in intestinal motion is wrongly associated with beneficial digestive or laxative properties of the fermented food. In reality, the body is trying to speedily eliminate a substandard food.

The idea that fermented foods could somehow make digestion easier probably came from the observations of people who could not tolerate whole milk but could eat yogurt or some other fermented milk product.

Over 70% of the world's adults cannot digest milk. They lack a digestive enzyme called *lactase* that is needed to digest milk sugar or *lactose*. Undigested lactose results in diarrhea, cramping and abdominal pains. Fermented milk products are low in lactose, and cause less discomfort than unfermented milk.

Two things should be obvious from this discussion. First, fermented foods (in this case, fermented milk products) are *not* aiding digestion, but instead are just low in one of the factors that may cause digestive distress (lactose). Digestion is always and entirely under control by the body. Foods cannot "aid" digestion anymore than they can aid breathing or circulation. True, unsuitable foods can disrupt digestion (like milk and its products) but it is fallacious to say that foods which do not disrupt digestion are in fact aiding it. Food is inert. It can do nothing. It is acted on by the body. It cannot perform or abet an active, organic process.

The second thing to be learned is that obviously milk and its products are not good foods for the human body. If a food cannot be enjoyed in its natural and unprocessed state, then it is not a suitable food for the human diet. If milk must first be fermented (or partially decomposed) before it can be tolerated, then why should it ever be used in the first place?

Remember that foods cannot improve digestion, be they papayas or yogurt or sauerkraut. Digestion is improved by allowing the body to rest from this process (fasting) and letting it regenerate its own capacities—not by swallowing a fermented and rotted food.

### **2.4 Eating Rotting Foods For Longer Life?**

The most romantic myth about fermented foods is that they can prolong your life. We are given images of 100-year-old Russians dutifully swallowing their yogurt or we're told about how every long-lived

people include at least one fermented food in their diet.

Here is a recent promotion for eating yogurt, perhaps the most popular fermented food: "Yogurt can cure ulcers, relieve sunburn and forestall a hangover. It can be used as a facial or as a remedy for malaria. It confers long life and good looks, prolongs youth and fortifies the soul...."

Stay young, live long and have your soul fortified—quite a claim for a dish full of soured milk. If only it were true.

The idea that fermented foods can prolong life is totally unsubstantiated. This belief got its start around the turn of the twentieth century when an over-enthusiastic researcher named Uya Metchnikoff visited the Bulgarians in Europe. He discovered they had the greatest number of people who had lived past 100, and most of these people also incidentally ate yogurt. He seized upon these two coincidents and tried to present them as "cause" and "effect" without any real research or facts.

Other health writers since that time accepted Metchnikoff's speculations as truth and let their imaginations run wild. The truth is this: *There has never been any validated research which indicates that yogurt or any other food has "life-prolonging" properties.* One nutritional researcher, Beatrice Trum Hunter, states that "the yogurt in the long-lived Bulgarians diet was by no means the entire reason. The generous quantities of home-grown vegetables and their stress-free lifestyle played the vital roles in health and longevity of these people."

It's always tempting to think you can eat yourself into a long life, and for those people who fall prey to that kind of thinking, the yogurt manufacturers can find a ready market.

A long life, full of happiness and well-being, has as one of its requirements that wholesome, natural foods in an unprocessed state make up the diet. In any case, fermented and rotting foods could not be termed wholesome or natural. In no way, should yogurt or any other fermented food be given "magical" properties by over-enthusiastic promoters and writers.

[Home](#) > [Lesson 37 - Fermented And Putrefied Foods In The Diet; Studies Of Other Junk Foods](#) > 3. The Harmful Effects of Fermented Foods

### **3. The Harmful Effects of Fermented Foods**

So far, we have only discussed the myths of the supposedly beneficial effects of fermented foods. Can we say that even though these foods may not be particularly beneficial that they are perhaps harmless? No.

Fermented foods are not only ineffective, but they possess harmful properties as well. We have already mentioned that many fermented foods are heavily salted or preserved with vinegar which makes them harmful. What are some of the other bad properties of these foods?

#### **3.1 The Side-Effects of Fermentation**

When foods ferment, or decompose, certain waste products are produced by the bacteria which break down the food. One of these byproducts is alcohol. Many fermented foods, such as soy sauce, contain a significant amount of alcohol. Of course the alcohol in fermented foods is usually a small quantity (unless the fermented food happens to be wine or beer!), but even small amounts of alcohol affect the cells of the body.

Ammonia is another product of fermentation. Fermented soy may be as much as 15% *ammonia*. Ammonia is dangerous enough as a house-cleaning agent. You certainly shouldn't be eating it.

Vinegar, in the form of *acetic acid*, also results from food fermentation. This acid gives fermented foods their sour or sharp taste. That sharp taste is a signal to the body that the food should not be eaten as it is harmful. Vinegar prevents the digestion of foods, so a food filled with vinegar and other similar byproducts would seem to be indigestible.

Another acid that results from fermentation is *lactic acid*. Lactic acid is a waste product. If you have ever exercised or worked harder than usual, you might notice a stiffness or soreness in your muscles. That stiffness results from a buildup of lactic acid in the muscles. Now eating fermented foods that contain lactic acid may not make you "stiff," but does it seem intelligent to eat foods that are already high in waste byproducts?

Other acids are also present in fermented foods. Carbonic acid is found in fermented foods and also soft drinks. All of these acids are the wastes produced by the bacteria which are feeding on the decomposing, "fermented" foods.

### **3.2 Fermented Foods Are Low In Nutrition**

The foods that are highest in nutrition are those which are eaten in their fresh, natural and unprocessed state. As soon as a food is tampered with in any way, nutrient loss results. The longer a food is held in storage, the lower it becomes in nutrition.

Fermented foods are usually processed or destroyed in some manner. After that, they are often stored and used over a period of weeks or even months. You can eat a pickle that was once a cucumber perhaps one or two years ago, but it is very doubtful if any of the original nutrients remain in that cucumber.

Many times, foods are first heated to a high temperature before fermentation is allowed to occur. Milk is first heated or pasteurized to kill off all bacteria. Then it is inoculated with a specific bacteria strain to ferment it into yogurt. The milk serves merely as a bacteria culture ground.

If heat is not used, then the food is often chopped, sliced, smashed or blended. A whole head of cabbage does not readily "ferment," but if you bruise and chop it to pieces, then the bacteria will do their natural job of finishing the decomposition process. Whenever foods are cut, chopped or sliced to start the fermentation process, rapid oxidation of the food and a nutrient loss occur.

Another reason given for eating fermented foods is that they are high in B-vitamins, or that they may somehow encourage the body to produce more Vitamin B12 in its intestines. Just the opposite may be true.

According to research, the levels of Vitamin B12 may be *reduced* by fermented foods. A Bulgarian report indicates that the bacteria within yogurt use the B12 *for their own growth*. The B12 in kefir (a fermented milk drink) decreases in proportion to its fermentation.

Instead of adding nutritional benefits to the food, fermentation decreases some vitamin and mineral availability.

We've explored the myths surrounding fermented foods and described some of the harmful effects that may occur from their use. Now it's time to name names and discuss each popular fermented food.

## 4. Types of Fermented Foods in the Diet

Various fermented foods are eaten all over the world. Fermented fish cake is a delicacy in Japan, while the Koreans eat pickled garlic. Our discussion of fermented foods is limited to those foods eaten in the United States.

### 4.1 With A Moo-Moo Here...

The most popular types of fermented foods in this country are those made from dairy products. We have already discussed the unsuitability of milk and its products as human foods, so we'll give you a brief rundown on other aspects of these fermented foods.

### 4.2 Yogurt

Yogurt has been aggressively marketed as a health food. It's been called the "perfect food" and "insurance for good health." The U.S. Department of Agriculture in its yearbook for 1965 makes this unqualified statement: "Yogurt has no food or health values other than those present in the kind of milk from which it is made."

Yogurt has also been advertised as the perfect diet food. Even on this point, yogurt fails. It is high in saturated animal fats, and although plain yogurt has 154 calories per cup, over 80% of all yogurt eaten is the sweetened fruit-flavored variety which has 275 calories a cup.

Research in the last ten years has pointed out another danger of yogurt: cataracts. A cataract is the cloudiness of the lens of the eye. In severe cases, it causes blindness.

In animal experiments, *all* animals that were fed yogurt exclusively for several months developed cataracts in both eyes. In parts of India where yogurt is a large proportion of the diet, the incidence of cataracts is very high. A coincidence? Doubtful.

Researchers finally decided that some individuals may develop cataracts if they eat foods containing high levels of galactose (a sugar less soluble and sweet than glucose). Yogurt is one of the highest foods in galactose. Most commercial yogurts are 22% to 24% galactose.

People that usually do not eat dairy products sometimes feel obligated to sneak some yogurt into their diet for "health" reasons. There is nothing magical or healthy about yogurt. Like all milk products, it should not be used in the diet.

### 4.3 Don't Say Cheese!

Cheese is a very popular fermented food. The harmful effects of this food have already been discussed in an earlier lesson. You may want to consider this fact: most commercial cheeses have their fermentation process started by the addition of *rennet* to the milk. Rennet contains the enzyme rennin which is found naturally in the stomach of a cow.

To get rennet to ferment the cheese, the stomachs of cows are scraped. These stomach extracts are then added to the milk for curdling the cheese. So, can you be a "vegetarian" and still eat cheese which is made with stomach scrapings of cows? Probably not.

Cheese is a food that is always rotting. Leave a piece at room temperature and you'll have blue, green, white and yellow mold growing all over it. Some people even like to eat this mold, but then some people will eat anything. You don't need "moldy milk" or cheese in your diet.

#### 4.4 Buttermilk, Sour Cream and Kefir

There are other fermented dairy foods besides cheese and yogurt. Buttermilk and kefir are two popular fermented milk drinks. Sour cream is exactly that: cream that has soured and gone bad.

Be aware that not only are these foods substandard because they are dairy products, but they are often adulterated before being sold. Buttermilk frequently has salt added to it; kefir is usually sweetened, and sour cream will have preservatives to keep it from becoming totally putrid.

#### 4.5 Vegetables You Can't Digest

A popular diet a few years ago allowed the dieter to eat all the pickles he or she could hold. If you wanted a snack, eat a pickle. If you had a meal, eat some pickles with it. Why? Because pickles are indigestible. They pass right through just as they were eaten, undigested and unabsorbed. There are better ways to lose weight than this pickle diet, but it does point out one fact: pickled and fermented vegetables are indigestible.

A cucumber is an excellent vegetable. It's crisp, slightly sweet, full of vital fluids, minerals, vitamins and amino acids. But if you soak that cucumber in vinegar and make a "fermented" food out of it, you've destroyed any beneficial properties it had. Digestive juices cannot penetrate pickled foods. They're like eating rubber. They pass right through you in the same small chunks that you chewed.

They are also heavily salted, spiced and preserved. They should not be eaten.

Although almost any vegetable can be fermented, the next most popular vegetable besides cucumbers for this purpose is cabbage. Sauerkraut is eaten in great quantities by some nationalities. Could it possibly be an acceptable food? Here is what T.C. Fry wrote about this food in 1981: "Sauerkraut is indigestible. The acetic acid (vinegar) that results from its bacterial decomposition is damaging to our digestive tract and inhibits the digestion and utilization of foods eaten with it. It is in the same class as all rotted foods."

#### 4.6 Where's The Joy In Soy?

Most of the fermented foods eaten in the world are made from soybeans. Of course, most of these fermented soy foods are chiefly popular in the Orient, but in the last few years they have greatly increased in use in this country as a result of the macrobiotic and other health movements. Is a fermented soybean good for you? You probably know the answer by now, but let's look at some of them briefly:

**Soy Sauce or Tamari:** This is the most popular fermented soy product. It is a liquid made from fermenting soybeans and sometimes wheat in large barrels. The end product is a very dark and salty liquid. It contains ammonia, alcohol and various acids. It is also 18% salt.

**Miso:** Another high-salt fermented food made from soybeans principally. It is used in great quantities by the Japanese, which in turn makes them the highest salt-consuming nation on earth. The Japanese also have the highest rates of stomach cancer on earth—a fact closely related to their high-salt intake of fermented and pickled foods.

**Tempeh:** This is not a very widely known fermented soy food yet, but it is being very aggressively marketed by private soy industries in this country and also by the Department of Agriculture. Tempeh is a cake of souring soybeans that have a heavy layer of grey-white mold growing all over them. This heavy layer of mold is somehow supposed to make the soybeans more digestible (incidentally, soybeans are probably the hardest to digest of all beans, none of which are easy to digest anyway).

Research in the last 15 years has shown that there are dozens of different toxins produced by molds. Different molds produce different toxins. Aflatoxin is the best known toxin and is a potent cancer-causing agent. All molds, however, produce their own unique toxin. Cooking does not destroy the toxins

produced by mold. Why anyone would desire to eat moldy foods is a mystery, but it is no secret that they are dangerous.

## 4.7 Other Fermented Foods

There are fermented grain products such as sourdough bread. There are fermented drinks such as beer and wine. Some health enthusiasts have devised fermented "nut" cheeses and saltless sauerkraut.

There are two things you need to know about these and all other fermented foods. First, these foods are not needed in the diet. They perform no function, provide no special nutrients, contain no "beneficial" bacteria and have no magical, life-extending properties. Secondly, all fermented foods contain harmful bacterial waste byproducts as well as possible salt, vinegar and other preservatives. In and of themselves, they are harmful to the living organism.

If a person follows the biologically correct diet of fresh, unprocessed fruits, vegetables, nuts, seeds and sprouts, he will have no perverse cravings for such spoiled foods. Eating rotting, putrefying and decomposing foods is an acquired habit, much like meat-eating and eating junk foods. Like these perverse habits, the practice of eating fermented and putrefied foods should be quickly abandoned by the dedicated seeker of health.

[Home](#) > [Lesson 37 - Fermented And Putrefied Foods In The Diet; Studies Of Other Junk Foods](#) > 5. Questions & Answers

## 5. Questions & Answers

**I think you're wrong. Whenever my stomach is upset, I can eat yogurt but any other food bothers me.**

Fermented foods may be "tolerated" by people with poor digestion because in actuality these foods do not digest at all! The body has the wisdom to recognize a spoiled and rotted food (which is what a fermented food is). It tries to hurry this food through the digestive tract to the anus where it can be quickly expelled and not disrupt the body. You don't digest a fermented food—you can only quickly eliminate it.

By the way, no food should be eaten on an upset stomach. People often make the mistake of eating something to "soothe" digestive upset. If you ever experience any digestive discomfort, that is a strong signal for you to skip or postpone your next meal.

**Almost every country in the world has some fermented food that they eat. Don't you think that means something?**

Tradition and popularity are the poorest ways to determine a proper diet. The only authority you should rely on when it comes to determining what is best to eat is your own body. In other words, the physiology and anatomy of your body are what make foods "acceptable" or "harmful" in the diet.

Your physiology will not accept fermented or rotting foods as a substitute for wholesome foods. Your body does not digest them. The waste products in such foods disrupt the digestion. The nutrient loss in fermented foods makes them unbalanced. Learn about the physiology of your body and the mechanics of digestion. These will tell you

more about a good diet than the mistakes made by millions of others.

**I make my own saltless and raw sauerkraut from fresh cabbage. I also have "yogurt" made from milk of blended raw nuts. I enjoy these foods and they have not been cooked, salted or so on, Why shouldn't I continue to use them?**

Let me ask a question. Do you actually improve the cabbage or nuts or whatever you ferment by this process? No. You have processed them either by blending, chopping, liquifying, grinding or whatever. You have fractured the foods and encouraged oxidation and nutrient loss. You have allowed fresh and wholesome foods to slowly decompose and rot from bacterial action.

What do you gain from all of this? Better health? Mysterious benefits? Nothing at all. If there's no benefit to fermented foods, why go to all the trouble of adulterating your food? True, you are using the best of ingredients with no harmful additives. But by encouraging these foods to putrify to give them a sour taste, you are wasting them and doing yourself no good at all.

[Home](#) > [Lesson 37 - Fermented And Putrefied Foods In The Diet; Studies Of Other Junk Foods](#) > Article #1: Excerpt from The Health Crusader

### **Article #1: Excerpt from The Health Crusader**

**If cooked and processed foods, meat, coffee, tea and other beverages are so poisonous, how come 75% of our population live to be 70 to 80, some even older? If dead food and poisonous foods are so bad, that doesn't seem right. There is some contradiction in your teachings somewhere along the way. Please explain.**

Your question really opens a can of worms! First, there are some unwarranted assumptions, namely that people live to be 70 or 80 on an exclusively dead food diet containing poisonous beverages and processed foods. That is not true. Most people do get raw foods almost on a daily basis. It is because of these foods that we survive as well as we do. The main thing humans require in their food intake is fuel, and cooked foods do furnish this. But they also give an unwanted product—poisonous ashes which result from the breakdown or destruction of food from heat. These poisonous ashes are not as readily observable as ashes in a fireplace or from a cigarette, but they are there nonetheless. Consuming ash-laden food is destructive. It is by a thin margin that we last as long as we do.

The human body is marvelously complex. It has hundred of defensive mechanisms to protect it against the ravages of poisons. The body has a tremendous capacity for throwing off poisons. But this capacity is best not used because each bout with poisons lowers our vitality until finally we become the whimpering suffering bunch that the majority of us really are. Did you know that over 50% of Americans suffer from some serious chronic illness? Did you know Americans suffer over 600 million colds a year? Did you know that 50 percent of American meals end up in indigestion? Did you know that 45 percent of Americans die of heart problems? Another 20 percent from cancer?

Humans are hard to kill—that's all that your question indicates. If we look into the factors of

longevity, we see that disease and suffering are very, very common among Americans. It's incredible that many live to 70 or 80! But, if we lived healthily we might live to well over 100 on the average—*without any suffering!* America is so bad off healthwise that I can say there's a 99% chance that you have bad teeth, a 72 percent probability that you have less than perfect eyesight (perfect is normal), a 50 percent chance that you have some nagging perpetual ailment, and so on.

Yes, it is remarkable that the human body can take so much punishment and yet survive. But that is no reason to continue the abuse of our highly-developed organism. It will be so much more serviceable and perform so much better if it is accorded the care it requires. In this regard it is like an automobile. But, unlike an automobile, we cannot replace it. Attempts are made to replace body parts but this is often unsuccessful or unsatisfactory because the body rejects alien tissues.

Do you know what happens to those who don't get enough nutrients and who consume junk food and other poisonous substances? Have you ever wondered why cancer is now our number one child killer? The truth is that junk foods, cokes and sodas, meats, eggs, etc. cannot make healthy (normal) cells. Without the minimum nutrients needed the powers of life wane and the poisons wreak their havoc until leukemia or other cancers result. One of the most prominent features of our way of life is our prevalent disease and suffering. The average Chinaman is a living example of fitness and well-being compared with the average American. Yet this is not to praise the Chinese mode of living. Rather, theirs is simply much less harmful than our own. They do so many more things that are right by their bodies than we do.

Americans play the game of Russian roulette with their bodies. But it's our life, not a game. Learn how to live healthfully. Then apply what you know. Put what you're learning into practice now.

- [Article #4: Junk Fooders Have It Made](#)

### 1. Introduction

#### 1.1 The Junk Food Problem

Junk foods are more than just something to eat. They also represent money, profits, past emotional associations, childhood indulgences, and high-power advertising.

The junk food problem is not simply one of nutrition, but is related to the economic structure of this country and to the psychological and emotional makeup of millions of Americans.

If you want to wean yourself, your friends, and your clients away from health-destroying junk foods, then you must also understand the true nature of junk food addiction. You must learn how junk food is promoted, and why we allow ourselves to become willing addicts to food that supplies no nutrition or fulfills no need in the human diet. In short, you must learn about the economical and psychological aspects of junk food.

#### 1.2 The 50% Junk Food Diet

More than half of all foods eaten by the typical American are junk foods. A junk food in this case means a food that is exceptionally high in sugar, fat or salt and supplies little or no nutrition. In short, a junk food consists largely of calories and little else.

Still, it is hard to believe that one out of every two bites eaten is a mouthful of junk food. Yet, it is true. Here's what the typical American ate last year:

#### 1.3 Junk Food Consumption of the Average American (Per Year)

1. Refined white sugar	100 pounds
------------------------	------------

2. Fats and Oils	55 pounds
3. Soda and Cola Drinks	300 cans or bottles
4. Chewing gum	200 sticks
5. Ice Cream	80 quarts
6. Candy	18 pounds
7. Potato Chips	5 pounds
8. Other snack chips	2 pounds
9. Doughnuts	63 dozen
10. Cookies and cakes	70 pounds

On the average, every man, woman and child in this country is eating about *700 pounds* of junk food each year. This does not even count other substandard and inappropriate foods, such as meat, alcohol, white bread, jams, jellies, and soon.

These foods have no nutritional value; indeed, they contribute to over 90% of all illnesses in this country. Why do people eat them? Obviously it's not for any food value.

No, junk foods are eaten for two basic reasons: 1) they are highly visible, heavily advertised and are a cornerstone of this nation's food dollar; and 2) junk foods exert a subtle but powerful psychological appeal for the user of such foods.

[Home](#) > [Lesson 38 - Sociological Benefits And Economic Ramifications Of The Avoidance Of Junk Foods](#) > 2. The Economics Of Junk Food

## **2. The Economics Of Junk Food**

### **2.1 Foods For Profit**

Junk foods exist today for only one reason: they are highly profitable. Because they can be marked up so heavily over the costs of production, junk foods put millions of dollars into the pockets of manufacturers.

It's a fact that the lowest-profit item in most grocery stores is the produce—the fresh fruits and vegetables—and that the highest mark-up comes from packaged, processed and junk foods.

Natural and traditional foods, like fruits, vegetables, nuts and seeds, are rarely advertised because they cannot be given a brand name or identity by a manufacturer. After all, a potato is just a potato, and worth only a few cents a pound. But if you slice that potato, boil it in oil, add a large dose of salt and

preservatives, and package it a bright bag with a catchy name, then you have potato chips that can be sold for ten to twenty times the cost of the original potato.

Even twenty years ago, it was discovered that for every dollar spent on breakfast cereals (a sugary junk food), only a fraction went for the cost of the raw materials. Consider where the average junk food dollar goes:

For Each Dollar Spent On Junk Food...

- 12 cents goes for packaging
- 17 cents pays for the advertising and promotion
- 55 cents goes for processing and profit-markup
- 6 cents is for additives, preservatives and colorings
- 10 cents is for the actual food in the product

In contrast, for every dollar spent on produce and natural foods (like whole grains, nuts, seeds, dried fruits), about 65 cents goes for the actual food cost and the remaining for transportation and retail markup.

Not only does the consumer of junk and processed foods pay in terms of health and well-being, he is also spending 5 to 20 times as much as he should for the actual food.

Here's another example: a popular "food" developed a few years ago was called "Shake 'n Bake." It was a food crust or covering put on chicken, fish and so on. It sold for \$2.63 per pound. It was mostly wheat flour, with a few artificial spices and coloring, that could be purchased for 15 cents a pound for its raw ingredients. The consumer was paying the extra \$2.48 for television advertising and promotion.

It's the advertising and packaging that make junk foods so expensive and so profitable. In fact, without mass advertising, there would probably be no junk foods. An understanding of the junk food problem, then, requires an understanding of the advertising and promotion of this food.

## 2.2 Creating a Need

Of all the products sold in this country, food is the most ideally suited to manipulation and deception. The consumer has a limited ability to evaluate the effects of food processing on its nutritional value. He has no idea about the long-term effects of food additives on his health. He cannot verify any of the claims made by the advertising.

Food should serve one primary purpose: supplying the materials needed by the body for its health and preservation. Junk foods cannot do this. In fact, they do just the opposite. In that case, it should be easily seen that there are no rational reasons to purchase or consume junk foods. There is no real need for them.

The manufacturers of these foods realize this. They also know that if they can create an imagined need for their products, they can get consumers to buy them. If you take a child that is raised away from the influences of television, peer influence, and deceptive advertising and ask him what he desires when he is hungry, he might respond with something like "an apple" or "a banana." He most assuredly wouldn't answer with "a Ding-Dong" or "Captain Chocolate Cereal."

Unless a junk food is advertised, we know nothing about it. Having no innate need for it, we wouldn't buy it. But if we are told that it exists and that we should probably try it, then we may fall prey to the advertising gimmicks of junk food salesmen.

Michael S. Lasky, author of *The Complete Junk Food Book*, has this to say about eating junk food and the power of advertising:

"We are all proselytized at an important age into consuming puppets of the junk food barons. Our parents inadvertently help them by buying their products as a form of 'reward' food. We grow up

unaware that we have slowly acquired a junk food habit by the subtle forces of advertising. By the time we are capable of making a decision about junk food, we are already hooked from years and years of indulging in what we had been told by TV was good food."

Actually, very little "good food" is advertised. Eighty percent of all food advertising is for blatant junk foods. Most of the remaining 20% is for convenience foods that are often little better than the candy, cakes, and snack foods which make up the majority of food advertising. In fact, out of the top 100 most heavily advertised food products, over 30 of them have absolutely zero food value, except for empty calories.

The majority of Americans receive almost all of their nutritional information from advertising. In other words, the typical person only knows as much about nutrition and good food as the advertisers want to tell him. When asked how good a job food manufacturers do in telling the public about good nutrition, a leading advertising executive for a convenience food company said: "The job of product advertising is to persuade and sell, not to educate."

Studies have shown that it does not matter how nutritious a food may be or even how good it tastes. It is advertising alone that sells a food product, and it is primarily the junk foods and the nonfoods that are advertised the heaviest.

## **2.3 Partners In Crime**

The manufacturers and advertisers of junk food are not the only ones to blame for our nation's ill health. Economics dictates that chain supermarkets and grocery stores must also be aggressive partners with the producers of junk food.

Walk into any grocery store and what do you see? Outside of maybe one aisle for fresh produce and the milk and meat sections, the rest of the store is filled with packaged and convenience junk foods.

Consider these facts: Eighty percent of all food items sold in the supermarket *did not exist ten years ago*. In the past decade, over 9700 new items were introduced into grocery stores. The majority of these items are packaged junk foods which are characterized by a remarkable lack of nutrients due to overprocessing.

That's right, your friendly neighborhood grocer is simply another of the links in the junk food chain—foods that the Senate Committee on Human Health and Nutrition say contribute to 6 out of 10 of the leading causes of death in this country.

## **2.4 Surviving The Supermarket Jungle**

More than 50% of all purchases made in a supermarket are done on a whim. You don't go to a grocery store with the conscious thought of buying frozen brownies or butterscotch chip cookies. The designers of supermarkets know this, and consequently they stack all of the high-profit junk foods in front of the consumer so it is impossible to avoid seeing them.

In a book called *The Supermarket Trap*, author Jennifer Cross says that even a person with a cast-iron will can fall prey to the junk food merchandising used in grocery stores. "The consumer's senses become so blitzed by the sheer amount of food choices that everything becomes a blur. Logic and common sense fail us, and we choose food items solely because of attractive packaging or name recognition."

The simple way to avoid such a trap is to buy only specific items from a supermarket. If you go into the store and head straight for the fresh produce department and come straight out, you can miss the cookies, candies and packaged foods that might beckon you. Most grocery shoppers make the mistake of pushing their basket up one aisle and down the other, exposing themselves to thousands of poor food choices and useless products.

Marketing studies have shown that from 70 to 90% of the time, the purchase of junkie favorites like

candy, frozen desserts, snacks and chips occur because of an instored decision. People do not consciously go into a store to purchase useless and destructive nonfood items, but once they are inside, they become fair game for the promotion and advertising tricks of the store.

There are two ways to handle this situation. The best way is simply to refuse to ever buy or eat such products. If junk foods are never a part of your diet, you'll never be tempted to buy them. Even if you eat them only on rare occasions, the potential for buying them will still remain. The second way is to make a list *before* you go shopping. Then refuse to buy anything not on your list, and always shop alone—without a spouse or begging children.

[Home](#) > [Lesson 38 - Sociological Benefits And Economic Ramifications Of The Avoidance Of Junk Foods](#) > 3. Junk Food Tactics

### **3. Junk Food Tactics**

#### **3.1 Candy Is Good For You And Other Lies**

Not only does the junk food industry aggressively promote health-destroying foods through advertising, but they defend them with a barrage of propaganda, misinformation, and outright lies. Much of this propaganda is aimed at children and concerned parents.

Consider the following statements that are in a booklet distributed to over 60,000 students by the National Confectioner's Association.

1. "Candy is vital for weight watchers. To reduce, eat candy before and after each meal. We can promise you it works."
2. "Candy helps fight fever and can prevent vomiting and diarrhea."
3. "Candy is not the cause of cavities, but the lack of hard chewing causes tooth decay."

Not to be outdone, the National Soft Drink association passes out literature to children and high school athletes that tell them "soda drinks are a good source of water." A better source of water is water itself—but then, you can't sell pure water for a hefty profit under some brand name.

Finally, read what the Hershey Foods Corporation has to say about proper nutrition in their "Nutritional Information" handbook: "Calories are important, and foods which supply only calories can, if used correctly, contribute to good nutrition." Of course, one of the highest calorie, no-nutrition foods is white sugar—a chief ingredient in this manufacturer's products.

#### **3.2 The Great Fortification Rip-off**

Besides deceptive advertising and outrageous propaganda, the junk food industry defends its products by emphasizing the added nutrients these products contain. "Fortified" candy bars and cereals are used to lure consumers into thinking that they might be getting a little nutrition among the garbage.

Here's how it works. Junk food manufacturers know that their products have no nutritional value and that their foods are open to attack by nutritionists. To head off such criticism, they often add vitamins and minerals to their products. Thus we have sugary bits of cereal that claim to supply 100% of all our vitamin and mineral needs. There are candy bars that give us "10% of all 19 nutrients" that we need.

Adding inorganic and useless vitamins and minerals to junk food is a cheap process. You can turn a box of sugared, processed cereal into a daily vitamin pill by adding about two cents worth of additives. In turn, these fortified junk foods are then marked up 15 to 25 times what it costs to add these useless

vitamins and minerals.

Fortified junk foods still have the white sugar, the saturated fats, the high salt content, and the empty-calories. The consumer is fooled by two cents of added minerals and vitamins. Even worse, the so-called "extra" vitamins and minerals which were added to the junk food cannot be used anyway. They are inorganic chemicals, just like the other additives and the preservatives already laced through the destructive foods.

### 3.3 Hooking the Kids

Children are the helpless members of our society. And they are the biggest target for the junk food pushers. Children know nothing about nutrition or the necessity of eating wholesome foods. They receive most of their knowledge from television programming and advertising.

Junk foods are advertised on children's television shows at the rate of 20 times per hour—certainly enough to qualify it as brainwashing. Robert B. Choate, a television critic, told a Senate investigating committee, "When you take a child who sits in front of Saturday TV and hears sugar, sugar, sugar, chocolate, chocolate, chocolate, he picks up a habit that is going to last all his life."

"Get'em while they're young" is the attitude of the sugar cereal and candy manufacturers. And they're successful. The Surgeon General's Scientific Advisory Committee found that junk food products advertised on television are more frequently requested by children than any other products, including toys.

"Television advertising," says Dr. Judith J. Wurtman and author on children's nutrition, "is probably the most persistent force undermining good-eating habits." One father who became concerned about his children's health threw away his television set after he became tired of salesmen in my living room telling lies to my children." Maybe you don't want to go that far, but here are some things you can do to counter the effects of junk food advertising on children.

1. **Fight propaganda with facts.** No matter how young your child is, he or she can understand some basic facts like "Sugar will make your teeth rot and hurt" and "Fresh fruit makes you strong and healthy."
2. **Restrict television watching.** Have your children watch commercial-free programs and stations. Try to avoid the heavy Saturday morning advertising schedule.
3. **Give your own reactions to commercials.** React with undisguised disgust at commercials for bad food or products. Point out to children how advertising is often deceptive. Don't let them think that television and advertising is to be trusted or accepted on face value. Teach them to think for themselves and to question things that they see or read.

If you're a parent, you will have a massive job in reeducating and protecting your children from the effects of junk food advertising. It is amazing that we have removed ads for cigarettes and hard liquor from television, but allow ads for "Sugar Puffs-Puffs" and "Chocolate Doo-Dads" to be blast into our children's brains at the rate of 5,000 per year.

Junk food addiction begins in childhood, and this is where the problem can be most easily handled.

## 4. Breaking The Junk Food Addiction

### 4.1 The Psychological Appeal of Junk Food

We cannot blame the entire junk food problem on the manufacturers and advertisers of these products. After all, if people did not eat such foods, they would never be kept in the marketplace. But people do eat junk foods. And they eat them almost compulsively, without regard to their health or to the innate harmfulness of these foods.

Why do junk foods exercise such a stranglehold on America's nutritional well-being? Primarily because such foods are psychologically addictive. A habitual use of junk food occurs not because the food is fulfilling any physiological need, but because they answer some psychological need. People eat non-nutritious, worthless foods purely for emotional and psychological reasons.

Psychological studies have shown that food is the single most powerful emotional stimulus in our lives. We use foods as much to cheer us up, to fight depression, to reward ourselves, to indulge ourselves as we do to satisfy any hunger, real or imagined. And because we often eat for emotional reasons, we often choose foods that are associated with specific emotional experiences. Unfortunately, such foods are often "pleasure" foods or junk foods.

"Most people do not eat foods because they are good for them," says Dr. Robert S. Harris, a professor of nutritional biochemistry at MIT, "But because the foods appeal to their appetite, to their emotions, to their soul."

Junk foods have a strong appeal to the primitive and infantile emotions. They are usually very sweet, very rich, and very filling. They remind us of our first rich and sweet food, mother's milk. They take the place of the natural sweets, like fruits, that our sweet tooth craves.

Junk foods are often the foods that our parents gave us for being "good"—ice cream, candy, cookies. Consequently, when we have been "good," we still reward ourselves with these foods. It is an early conditioning that persists long into adulthood.

It is interesting to observe that junk food is the single largest class of pollutants that modern man *inflicts upon himself*. Forget about air pollution, cigarette smoke, contaminated water, radiation, or so on. It is the junk food eaten everyday by almost every person in this country that is the biggest source of internal pollutions. Now psychologically, this is an interesting situation.

Junk foods, besides being a way to reward ourselves, now also become a way to *punish* ourselves. People who are depressed and who have a low self-esteem often eat health-destroying foods in an effort to punish themselves for being unworthy or for having committed imagined wrongs. Junk food becomes for these people a socially-sanctioned form of suicide.

A successful avoidance and elimination of junk food from the diet requires efforts from two sides. First, a barrage of nutritional information and hard facts about the destructiveness of these foods must be obtained. Second, the person's psychological state must be evaluated and improved so that this addiction can be exposed and eliminated forever.

### 4.2 The Economic Benefits of Avoiding Junk Food

Nutritional arguments for the elimination of junk food may not be effective enough to wean people away from a poor diet. Almost everyone, however, understands the benefits of saving money. Eliminating junk food not only results in better health, but it means a real savings in the amount of money spent every day.

Let's look at the typical costs for a junk food habit for the average person. During a week, every person in this country is calculated to consume, on the average; the following amounts of junk food:

### **One Week of Junk Food And Us Cost**

- 7 bottles of soda
- 1 package of gum
- 2 quarts of ice cream
- 2 ounces of snack chips
- 1 dozen doughnuts
- 1 pound of cookies or sweets
- 6 ounces of candy

1982 costs for such foods: \$16

Notice that the above does not take into consideration any fast food eaten out or convenience foods prepared (such as frozen desserts, sugared cereals, etc.) The average spent on such foods per week varies greatly, but a conservative estimate of the costs of such foods per week is around \$18.

Not only do these junk foods and fast foods cost money to eat, but the after-effects of consuming such foods often results in additional money being spent. Indigestion, headaches, colds, hemorrhoids, colitis, and many other ailments may be traced to junk food consumption. The average person may spend another \$5 per week just on "medicine cabinet" remedies or over-the-counter drugs for these illnesses that result from such foods.

A year of junk food eating also typically results in about six new cavities and a tooth needing capping or pulling, according to figures from Army dentists. This translates into an average \$10 per week for dental care.

We still do not know the costs of medical expenses that accumulate because junk food eaters go to their doctors, nor can we accurately figure in how many lost days of work result from such a diet. Even so, the total costs of eating junk food for a year are impressive. Consider these 'figures:

### **Annual Costs of a Junk Food Diet**

Junk foods	\$832
Fast foods	\$936
Drugs and Medication	\$260
Dental Bills	\$520
Medical Bills (estimate)	\$250
Days lost from work (estimate)	\$350
Total yearly loss of income from junk foods	\$3,148

By eliminating junk foods from the diet, a person would realize enough yearly savings to purchase a new car every three years. He or she would have more energy, a higher level of health and well-being, and literally extra years to enjoy such benefits. No one really knows how much junk foods shorten the lifespan, but it would probably not be unrealistic to use the same figures that are often quoted for cigarette smokers. Every cigarette smoked means a 15-minute decrease in your life. Junk foods, with all their poisons and additives, may be more harmful than smoking and it would not be unreasonable to assume for every bag of cookies or quart of ice cream, you're knocking off hours, days, and weeks of your life.

Understand that these figures are speculative and have no sound basis in hard research simply because no one has had an opportunity to study the long-term effects of eating junk foods. We are the first generation of guinea pigs for the high-sugar, high-salt, high-fat and high-poison junk food diet.

Regardless, it is painfully obvious that people who consume junk foods not only steal money from themselves and their families, but also lay the foundation for expensive and painful suffering in the years to come. Can any type of food or sensual pleasure be worth these costs? Is a chocolate chip cookie or a scoop of ice cream or a diet soda worth \$3000 plus a year?

The next time someone says to you, "I'm just dying for a piece of that cake or pie," you should let them know that that is just precisely what they are doing, and they are also paying dearly for this "privilege."

#### **4.4 Kicking The Habit**

As we have seen, the junk food problem is not simply one of nutrition. Good nutrition is easy to teach, but is only partially effective in getting people away from their junk food habits.

People must also be made aware of the economic and psychological aspects of eating junk food. This lesson should help you educate others who are ready to abandon the typical high junk food diet of most Americans.

First, teach the person the economic facts of life about junk foods.

1. Junk foods are very expensive to eat in terms of the actual nutrition provided. Most junk foods have only about 10% of the food you are paying for. The rest is for pretty packaging, promotion, advertising and profits.
2. Junk foods cost you twice. Once when you pay the overinflated prices for them and again when you pay the costs of ill health that they produce.
3. A typical overfed American family can save anywhere from \$5,000 to \$10,000 a year if they eliminate all fast foods and convenience foods from their diets. This saving results from the actual costs of the junk food, the sick time lost because of them, and the incidental expenses of eating such foods.

Second, the person must be made aware of the psychological reasons for junk food addiction. He should be told that most eating patterns are based on emotional and not rational decisions. Foods as a reward or punishment should not be used—neither for children nor adults.

Negative eating habits and poor choices sometimes result from a lack of self-esteem or self-worth. A person addicted to junk food may have other serious problems connected with the personality or with social behavior. To eliminate junk foods from such a person's diet, he or she must also embark upon an overall health program of improvement. They must view themselves in a different light, and consider themselves worthy of good health and sickness-free living.

Third, children are especially vulnerable to junk foods. Outside of rational explanations and setting a good example, you can wean children away from junk foods with healthy substitutes. Sweet dried fruits can replace candies. Fresh juices or blended fruits can take the place of sugary drinks. Realize that most children want the sweetness of junk foods because they have a natural sweet tooth and demand for high-carbohydrate foods that can supply them with energy. In this case, give them plenty of natural

carbohydrates with fresh fruits, dried fruits and occasional nuts and seeds.

The way to fight junk food addiction is through education. Tell your friends, your family and your clients about the nutritional inadequacies of these foods. Let them see the economic harm that also comes from consuming such foods. An approach to this problem on several levels—nutritional, economic, and psychological—can help most people end their romance with junk food and give them years of healthy and illness-free living.

[Home](#) > [Lesson 38 - Sociological Benefits And Economic Ramifications Of The Avoidance Of Junk Foods](#) > 5. Questions & Answers

## 5. Questions & Answers

**There's one aspect of junk foods that you overlooked. The ecological benefits from avoiding all junk foods.**

Thank you. That is also a very important area, and it may help some people end their consumption of these foods. Ecologically, junk foods are a disaster. Right now there are millions of acres of trees and rain forests in South America that are being destroyed forever by a major hamburger chain. They are clear-cutting trees hundreds of years old so that they can raise more cattle at a cheap price for their hamburgers. Not only that, but millions of trees are sacrificed annually so that these hamburgers and french fries can be packaged in paper and wrappings.

Junk food is a rich source of both external and internal pollution. Litter from junk food products is astounding, and it is everywhere. My family and I were once picking peaches in a large orchard that allowed the public to pick and eat all the peaches they wanted., We were happily picking and eating tree-ripened fruit right in the orchard. Suddenly I noticed that all over the grounds of the orchard were candy bar wrappers, chip bags, empty soda cans, and bags from rake-out fast food places.

Here were thousands of luscious fruits all around us—the natural food for man, and the best available, just for the picking. What were people doing? They were bringing in bags of junk food and throwing the remains on the ground. They had become so blinded and desensitized by their addiction to junk foods that they could not even recognize wholesome foods that were literally hanging before their very eyes.

Not only that, but after eating such foods, their consciousness was so deadened that they threw the trash and garbage from these foods all around them. It's sad, but people that eat junk and trash foods often act trashy. There is no way that you can claim to be concerned about the environment or ecology and still eat junk foods. It's a contradiction, and junk foods are a significant part of the pollution affecting our planet.

**My problem is other people. They all think I never have any fun because I won't eat their "fun" foods, like potato chips and cookies. They tell me that I'm cheating myself out of some simple enjoyments. What should I say in return?**

The main problem with junk food is that so many people see it as a harmless pleasure or as a legitimate form of entertainment. Food should be pleasurable to eat, but too often it is used just as social entertainment. Why people think that you must eat health-destroying foods to

be sociable is a mystery. Often you will find people that eat junk foods do indeed know better. They realize that they are making poor and incorrect food choices, and no doubt they unconsciously resent it when you do not "join in" and give your support to their bad habits. Probably the best thing to say when offered junk foods is a polite and smiling, "No, thank you" without any further explanation. If you're pressed, simply say that you feel much better when you don't eat such foods. Make it sound like your rejections of these foods is a personal choice and not an attack on their dietary habits.

People dislike being told that they are doing the wrong thing—especially when they already suspect it. By remaining pleasant and exhibiting a well-balanced attitude toward such foods, you may make a positive impression on the person and thereby encourage them to also give up junk foods. By no means should you lecture to the person or point out how much better you are than them. A well-balanced, healthy person is usually a strong enough argument for the avoidance of junk foods.

**My friends always tell me that fast foods are a cheap way to eat dinner, and that they really couldn't afford to eat just fresh fruit and vegetables. Now you say that these foods are actually costly. What's the truth?**

Fast foods are deceptive. Certainly you can fill your stomach up for every little money, but this "full" feeling is because of the heavy amounts of grease and fat present in these foods as well as the cheap white bread and filler that they use.

Junk foods may seem like a cheap way to fill up, but they are an expensive way to get nutrition. *Proper eating is not just having your stomach full.* When these same people who get a cheap meal at a fast food place later have to pay hundreds of dollars on dental or medical care, they don't see the connection. When they later have cancers, heart problems, kidney failure and premature aging, they never suspect that they are results of too many "cheap" meals.

You cannot cheat your body of the nutrients and foods it needs by just "filling it up" with cheap, greasy bulk. The best way to eat inexpensively is to select those foods that promote the highest level of health—regardless of financial costs. You see, even if you spend twice as much for good foods than for junk foods, you're avoiding the much greater expenses of pain, suffering and ill-health.

Junk foods are nutritionally worthless and health-destroying. Yet they still make up, half of the average person's diet. Why? Because the economics of junk food production and promotion make them a high-profit and a highly visible item.

People are first manipulated by the manufacturers into buying junk foods, and then they are controlled by their psychological addictions to continue eating the foods.

Eliminating junk foods from a person's diet depends upon a three-fold approach. First, intensive nutritional education. This is the rational appeal. Next, a concrete illustration of how much money can be saved if junk foods are eliminated (actual costs of the foods, expensive sicknesses caused by such foods, etc.). This is the material appeal. Finally, an explanation of the psychological factors in eating junk foods (how they serve as an emotional substitute, how they are used to "reward" or "punish.") This is the emotional appeal. An education program of this sort is effective in breaking the junk food addiction.

## **Article #1: Control Through Clear Thinking by A.D. Andrews, Jr.**

I have a Master of Science Degree in Health Education. Also I have been certified (for life) by the State of Missouri to teach classes in Health. This presentation of personal achievement is supposed to impress you. It is important that I make a big impression on you at the beginning of this article because I am getting ready to make some highly unusual statements in the very next paragraph and I want you to pay close attention to the statements and to follow the advice which I offer.

If you are going to eat anything besides raw foods, namely fruits, nuts and palatable vegetables, then eat the junkiest foods you can get. Eat canned foods, processed foods. When you cook at home cook out of aluminum utensils. Peel all vegetables and boil them thoroughly. Fry foods in cast iron skillets at high temperatures using saturated fats and oils. Apply salt, pepper and other condiments freely. Pay no attention to combinations. Eat as much as you can stuff down. Have rich desserts and drink liquids with your meals.

Now my earnest advice is for you to eat no cooked foods, only raw foods. However, if and when you "slip" eat all things bad and nothing good. I am completely earnest. Here is why. It will make you quite ill, quite soon and shake you up. It will bring you back to your senses, put you back on the straight and narrow. You may even decide to fast for a day or two to keep your wits about you for an extended period of time. It will precipitate or *stimulate* symptoms of acute disease. You will have no difficulty relating cause and effect.

It helps clear thinking if we learn to think through analogies. A number of years ago friends of mine were "busy-busy" working for the enactment of a "humane" slaughter law in the state of Missouri. They were disgruntled that I fought against this bill. (It passed, by the way.) Why did I fight against it? People already are too far removed from the act of slaughter and what it entails. The attractively arranged meat platter with garnish and color seldom is connected with the violence it took initially to bring that pleasing plate to the table. Those appealing prepackaged meats on display in the local supermarket are a far cry from the appalling brutality of the slaughter house. So the very thing that is needed is whatever is at hand to make people see flesh eating for what is really is, a barbarous, gruesome, ugly, cruel practice that destroys human morality as surely as it destroys the animals we kill. Flesh eaters need to see their flesh in stark reality as corpse rather than prime rib, as carcass of a dead animal instead of K.C. steak, as cesspools of putrefaction rather than as sources of complete protein. Already people are mired and bogged in the slough of a vile practice. The last thing they need is further lulling with thoughts that it all has been accomplished "Humanely." And the long-range effects of any practice that benumbs man's noble instincts of kindness and concern for creatures less able than himself are more dangerous and devastating to his final demise than the damage done by the pathological effect of meat-eating on his body.

People are rather fooled in their minds with the seriousness of an offense (in any area) in relation to the overall harm that is done. They assume, for example, that arsenic is more "dangerous" than, say, fluorides in public drinking water. They assume this because they see an arsenic victim agonize and die on the spot. The fluoridated water drinker seems to go on day after day and live out his "normal" life.

The truth of the matter is that one man takes arsenic and dies. Many people see the result of this, see it quite clearly. They understand what they saw and no one ever considers taking arsenic purposefully or accidentally. He fears and runs from arsenic, arsenic compounds or anything containing or thought to contain arsenic. One dies; many live.

However, the man who "thinks" it's a good idea to drink only distilled or filtered or mountain stream water, may, at inconvenient times, get caught thirsty in an office building or a friend's home or he may just react mechanically as he passes a drinking fountain and take a drink of fluoridated water assuming

in his mind that "It won't kill him." But when the sum total of all the damage to all life done by drinking and using fluoridated water is considered, it will be recognized that far more damage has been done than was done by the one dose of arsenic from which many learned their lessons. Here, no one learns. To the contrary all are lulled into the acceptance and further practice of something which gradually will leech the health potential of the entire nation. And down, down, down we shall go until we know again the company of the dodo bird!

This one practice is only one of many things we do that sap us, drain us. And it is our rationalization of each one's being only a minor thing. We wrongly see narcotics as being more harmful than candy; alcohol as being more dangerous than white bread. The list could be added to indefinitely. We see the big lie as sinful but the white lie as expedient. We view the robber and the thief with disdain but tell our own children to lie about their ages to enter cinema or ride the bus for less cost. Less cost, my eye! The bombing of a Birmingham church that kills little children is horrible, I agree. But, at least it shakes up and horrifies the total nation and causes it to examine its conscience. And the damage done is nothing when compared to the insidious moral erosion that takes place day after day, year after year, by individuals collectively and sustainingly thinking, feeling, voicing little hates, biases, prejudices against other human beings for any reason be it race, religion, business or politics.

Why is man forever fooled and deluded by the obvious? Why does he clutch so tenaciously to a dollar bill and look so disdainfully upon a penny? It is recognition of this foible that makes beggars rich! And it doesn't matter what be the area—food, drink, health, crime, morality, everything. It is not the big, obvious things we have to fear. We know the big things for what they are. We have no trouble relating big things to their results, to the damage they do.

It is a little thing done over and over for a long period of time that does widespread, irreparable harm. It is the variety of little things which when considered in aggregate kill individuals and nations.

Let us work to broaden our picture of the present to include yesterday and tomorrow, yesteryear and the years ahead. Let's become aware, really aware that an act is the same as the result of an act. Cancer is horrible! It is ugly, painful, frightening, stinking. No one argues this. And if this be so then all things that lead or contribute to cancer are ugly, painful, frightening, stinking! It cannot be otherwise.

So, if you see a single, occasional, sociable cup of coffee, with an old friend as being "nice," then brother, you are blind! And a blind fool at that...because coffee and stomach cancer are related. They are one and the same. And if you say, "So what, I'll run the risk for the pleasure of the moment," then, brother, not only are you a fool, you also are insane!

If a man is sitting in the middle of the floor hitting himself in the head with a hammer you have no trouble adjudging him as nuts. And because he says he enjoys each blow knowing it will finally destroy him makes him no less crazy. There is no difference between him and ourselves except that we have more company.

We will be wise to examine all our practice's in unemotional, unfettered light without reference to immediacy of pleasure, custom, tradition, conformity, external appearances, likes or dislikes. Examine these practices and determine one by one whether they are good or bad, healthful or harmful, right or wrong. Not just a little bit of one and a little bit of the other. Remember that nothing can be innocuous. Make it clear cut, black or white, no grays. And most important of all! Remember that the less harmful it seems to be the more dangerous it actually is to the greatest number of people over the greatest period of time.

And when you pick out the harmfulness of a practice, no matter how small and insignificant it may seem to be, then relate it to the big damage to which it contributes later on. When you do this you will see the little practice for what it really is. Also, and just as pregnant, you will see the big damage for what it really is. A morally sick society is made up of morally sick, singular persons. A war is but the remote extension of conflict and greed at the level of individuals. Hardened arteries are but the accumulation of many single deviant acts each of which seemed delightful at its moment but none of which can be

recalled a day after it has occurred.

It can be no other way. Can it? Do you see the big point I am making? War never caused greed, greed causes war. Hardened arteries never caused a man to eat greasy foods; greasy foods easily can be related to hardening of the arteries. Think about it. Come to understand that any practice, any action or reaction, anything that you do that you can recognize to be against your inner sense of well being, your fitness, your longevity is bad, wicked, sinful, evil and must be seen in that light. To see it in any other light is illusion, delusion, unreal. You don't have to be a college graduate to understand these things. (In fact, it may hinder your clarity.) All you have to do is to be quiet within yourself and think. Don't "work" at "think," just be still within yourself and the message will come through. Try it. You'll see. Life will be less hectic. "Control" will come easier, because when one really understands, he understands with his whole, entire self—not just with his mind. And when there is understanding, change in behavior comes. You don't have to "struggle" or "fight." Just learn to broaden your concept of today to include yesterday and tomorrow, yesteryear and all the years ahead. If you do, there will be more of them. They will be better ones too.

[Home](#) > [Lesson 38 - Sociological Benefits And Economic Ramifications Of The Avoidance Of Junk Foods](#) > Article #2: Is This The Kind Of System You'd Like To Live Under?

## **Article #2: Is This The Kind Of System You'd Like To Live Under?**

In this country we have what is called the capitalist system. Its sole motive is to produce for profits. The other day we received a brochure from LITTLE FREE PRESS that points out some of the inhumane drives of our present system. LITTLE FREE PRESS advocates a system that involves a non-money non-credit economy...a very challenging concept. I have embellished their points somewhat but they areas follows:

1. The establishment (capitalism as a system) is rapacious and indifferent to human welfare. It places private profit above peddling of pernicious products by the tobacco industry, the drug industry, the junk food industry and the recent mass manipulation of fuel supplies to jack up the prices of petroleum products—price hikes that bore no relationship to costs...charges all the marketplace will bear.
2. Polluting air, land and water is more profitable than recycling wastes in most cases or in installing equipment to prevent its release into the ecosphere.
3. In nuclear energy human safety and welfare have been subjugated to the quest for profits. Nuclear wastes are a legacy that can boomerang very quickly on us and keep posterity on the hook if not, indeed, outright suffering, for perhaps thousands of years.
4. War and war industries are more profitable than peace.
5. Planned obsolescence is more profitable than quality. Goods that will wear out faster are thus put on the market. Things are made for use, yes, but industry needs repeat customers to keep sales and profits high. If an automobile lasted in great condition for 50 years (as Rolls Royces do), the automobile industry wouldn't come out nearly as well as they presently do. Deliberate waste of human and material resources is built into a system geared to the profit system.
6. Discontented and unhappy people can be exploited for more profit and happy people.
7. Sickness and disease are the bases for profitable industries. Healthy people are not customers for disease treating business. Inasmuch as the petroleum industry, the drug industry, the hospital industry and the medical trades need diseased people for their profit-geared operations, they will fight tooth and nail steps that threaten this cushy racket of trading upon suffering and misery.

8. Cultivating an atmosphere of fear, mistrust, ignorance, confusion and nurturing outright lies and myths are a basis of great profit whereas an informed people shun the whole thing.
9. Overconsumption, overbuying, needless buying, ostentation (keeping up with and ahead of the Jones) are encouraged that the beneficiaries of the system might realize more sales and profits.
10. People who think for themselves and who get off the commercial treadmill are a threat to the system whereas those who unthinkingly accept the system and who bask in the superficial "roman circuses" designed to mislead and allay human intellect are the raw material from which much profit can be derived. In short the thrust of all commercial endeavors is to create a populace that accepts the status quo of the profit system, glossing over its injustices, its inhumaneness and its predisposition to churn out human wreckage rather than dignified humans.
11. Disposable products are more profitable than durable ones. Even though it is wasteful of our resources forest by forest, we cite as an example the use of paper towels versus fabric towels. Fabric towels can last years. One towel represents perhaps a \$2 value. Over the same period one individual might use fifty or sixty rolls of paper towels that cost \$40. The use of the one conserves resources, the use of the other expends them prodigally. America is geared to a "built-in wasteful system."
12. Making things unduly complex, mysterious and inscrutable is more profitable than making things simple.
13. Monopolies and controlled markets are more profitable than free trade.
14. When people have accidents, suffer from illness, catastrophe, etc. there is profit to be realized. A content and happy people are a poor market.

Thus you can see how inverted and perverted our values are.

I'll end quoting Ernest Mann, author of the piece:

"If we don't switch our method of "economic motivation" soon, our striving for profit may ruin our life-support system beyond the point of no return."

What is your role in this great play? Are you a tiny gear that helps to keep this juggernaut rolling? Could you find a way to survive without working for a company that is destroying our environment? Are you adding to people's distractions, to keep them from becoming aware of viable alternatives? Or are you helping others to become aware of our problems and turning them onto the solutions?

[Home](#) > [Lesson 38 - Sociological Benefits And Economic Ramifications Of The Avoidance Of Junk Foods](#) > Article #3: Blueprint For Survival by Keki R. Sidhwa, N.D., D.O.

### **Article #3: Blueprint For Survival by Keki R. Sidhwa, N.D., D.O.**

The great international debate today is not about the imminence of internecine war or the morality of nuclear weapons. It is about the quality of life that we may expect in the future for ourselves and our children. The important question now is—can the human race survive in terms of our present day relationship with the world outside and nature and, if we do manage to survive, in what state of health or ill health?

Are we heading for doom, come what may, or do we still have a chance? In which direction is the world heading?

There is no easy answer to the question. The web of life that nature has woven on this finite plant is immensely complex, full of subtle balances and involved interplays.

*Natural Hygiene* has always, from the beginning, demanded that we understand this scheme of natural balance. Now it seems the time is approaching when we either pay heed or pay the consequences. Instead of exploiting the natural resources we must learn to conserve and thus try to achieve once more the balance that nature achieved on earth before the impact of man and his "technological achievements."

Not only must we understand how man has disturbed the balance, but learn what steps we must take to rectify that mistake. Have we the will to make the changes we must make? Have we the power? I do not know. But, if only because of our growing understanding of our plight, I still hope.

The more of us who try to live a *Hygienic Life*—the better it is for the world also. *Natural Hygiene* is not smug isolation from the rest of the world. It is total commitment on behalf of the whole of mankind and the animal kingdom. The fact that you benefit also is incidental—a sort of bonus for the total involvement with the rest of life. By observing the following blueprint for the individual you will help the human race to survive:

1. Try to control the size of your family unit by natural means.
2. Use durables rather than disposables. Boycott over-packaged products, especially in plastics and aluminum and anything in nonreturnable or aerosol containers. Take your empties back to your store and tell them to re-use them.
3. Keep pesticides out of your home.
4. Boycott convenience foods and eat natural whole foods rather than fragmented foods. Use the wild foods that grow near you. Grow and preserve as much as possible. Eat vegetable rather than animal protein. Buy insect or virus blemished foods, they are less likely to be polluted by pesticides. Eat to live, not live to eat. Enjoy your food by all means and get all the pleasure out of it that you can, but don't be greedy. Overeating is not only a crime against your body, it is a crime against all living creatures. Getting the most out of your food is an art that only Hygienists have perfected.
5. Use building materials from reclaimed industrial waste.
6. Insulate your house well and cut your energy consumption. By getting plenty of exercise and keeping fit you maintain body warmth through efficient circulation. In winter put on extra clothing, keep moving and save heating fuel.
7. Water shortage—then shower instead of bathing. Never flush poisons in the W.C. Boycott detergents.
8. Use low wattage for light bulbs. Make the most of natural light. Let light, sunshine and air into your house. In order to conserve power do things with your hands. Use machines only when absolutely necessary.
9. For transport use a car with fuel economy in mind. Use a bicycle to go about in your town or village. Avoid lead-additive gasolines.
10. In your daily life use both sides of paper in writing. Pass on outgrown toys and clothes. Compost all organic waste. Garden without pesticides, herbicides, chemical fertilizers, etc.
11. In your community organize a local recycling club for glass, paper, cloth, iron and steel.
12. Monitor all local government plans for their environmental effects. Press for maximum recycling, especially of water in local industries. Press your local authority to make compost out of sewage.

In the final analysis we have to realize profoundly as *Natural Hygienists* that all our studies, deep and superficial, whether through books or by direct and personal experience in any form, cannot be divorced from living.

We can have more life, only if we help to enhance the whole of life.

*Reprinted from Dr. Shelton's Hygienic Review, January 1977*

### **Article #4: Junk Fooders Have It Made**

The University of Montana conducted some experiments on the food preferences of five-year old children before and after exposure to TV food commercials. "Natural preference" and preference after exposure to TV food commercials were compared.

The children were free to choose from junk foods such as corn chips, sweet cereals, cookies, soda pop, etc. and from higher-nutrition foods such as cheese, carrots, grapes, apples, milk and orange juice. Their natural preference was measured based on this simultaneous exposure.

Then the children were shown a mere 12 minutes of children's programming that included a half-dozen commercials for both low nutrition foods and for the higher-nutrition foods. Then back to the food tables and guess what?

The children consumed more junk foods and less higher-nutrition foods than in the previous exposure. Moreover, the children were more excited about the junk and had more recall of the junk food ads than of the other food ads.

It would seem the junkier your food products are, the better chance you have of selling them through TV advertising.

- [Article #3: Patients Dilemma: Who's Taking Care of Them? By Mrs. Elizabeth McCarter](#)

### 1. Presenting The Universal Problem

#### 1.1 Man Is Confused

Rod sat in a chair across the room rubbing his knees. From time to time his body would jerk and he would squirm in his chair as if ill at ease or uncomfortable for some reason or other. He recounted a sorry tale of how he had sought relief from many physicians and medical specialists for the constant pain which had limited his productiveness both socially and in the economic world from his early childhood and which was now causing him to quit his job as an accountant in a multi-national corporation because he could no longer hold a pen or pencil between his fingers.

The young man, just past thirty, recited an array of drugs and supplements which he had dutifully swallowed per the instructions given him. The drugging had begun at the age of two years when he had "come down" with a muscular rheumatism. It had continued unabated to the present day. Even as he spoke, Rod pulled from his pocket the latest prescription, deadly prednisone, and a bottle of a well known and highly advertised multiple vitamin-mineral supplement. Pitifully, Rod cried, "Can you help me? I have nowhere else to go!"

Unfortunately, Rod's story is only too common in today's pseudoworld, a world where humankind has been taught to live in a fantasyland of unreality, to believe that humankind can go on indefinitely defying the laws of living structure, that we can eat what, when and how we please, that we can continue to abuse our bodies, that we can take all manner of vile liquids, pills and potions into our bodies, that we can inhale foul air and make all manner of mistakes and not have to come face to face with the realities of our organic existence if we only have recourse to the supplement products offered, for a price, by the huge industrial giants of the times in which we live.

#### 1.2 World Health Statistics

As a result of this kind of foolishness, an insidious creeping debilitating force is at work among the peoples of the world, and especially in this country, with many being troubled by the sickness they see around them and their own eroding well-being, but not knowing what to do or where to turn for help.

The World Health Chart for 1968 shows the average age of males at death in the United States is 66.6 and females 74.1; 25th place for men and 14th for women, respectively among all the nations in the world. In recent years we have dropped from an earlier and now out-dated rating of 15th in spite of the fact that the supplement- and drug-related businesses have skyrocketed in sales and dollar volume. The

people have lost confidence in the medical profession.

### **1.3 Philosophy of Modern Medical Practice**

The whole history of medicine is one of palliation and stimulation. If you are sick, you take the proffered pill and make the hurt go away. Are you tired, unable to cope? No matter, just take this vitamin, that herb, a little wine or smoke the weed and swallow a packet of man-made inorganic or fancy synthetically chelated minerals and your body's vitality battery will be recharged, your mood elevated, your cares soothed away and all problems solved; the sun will shine in the sky and the world will lie at your feet. *It is too good to be true!*

We are a sick nation and getting sicker with every passing moment. We have not learned that, only nature can heal, that health will have none of forcing, but must be maintained and built through wholesome eating and living.

### **1.4 Supplementation**

Dr. Elizabeth well remembers that when she was a child her mother kept a veritable cupboardful of patent medicines: there was cod liver oil in the form of Scott's Emulsion, Dr. Lydia Pinkam's Tonic for Women; and others. There was always a tin of aspirin tablets on hand to relieve the headache as well as a special box of baking soda to soothe acid-troubled stomachs.

You see, at that time, vitamins were a totally new and unexplored area, but the family always had recourse to Grandma's green "tizzy," a green drink made from selected herbs which grew in the garden, guaranteed, of course, to "cure" any ailment.

Dr. Robert's childhood and early years were no different, even though his father was a medical doctor, a specialist in anaesthesiology at one of the large hospitals in the East. The "remedies," of course, had different names, fancy medical names, but the effects were the same: palliation and stimulation.

Now, we live in modern times. During the past fifty or so years, patent medicines have, for the most part, disappeared from the pharmacist's shelves and the home cupboards have been replaced by a collection of bottles of all kinds containing all manner of supplements: vitamins, enzymes and minerals especially, but also others. The drugs of our father's time have also largely disappeared only to be replaced by newer and more potent drugs because the others failed to fulfill the promises made for them—as these will also fail.

"Health" food stores are now found in almost every major and minor shopping center from Maine to California and in countries overseas, all offering all manner of magic ways to restore radiant health to a deeply troubled public eager to buy their offerings. We know many elderly people living on Social Security who trudge wearily into health food stores paying out huge sums for pills and potions which they firmly believe will bring them youthful zest and vigor. Yet all the while they continue their life-destroying practices and drag through the days of their lives ever hopeful that the "magic" of pills will give them back the youth of their childhood.

### **1.5 Is Supplementation the Answer?**

Is it true that because the vast majority of people now live in cities where admittedly the quality of the food is something less than ideal, that we must supplement our diet in order to have any hope of achieving and maintaining a reasonable level of health? Rod, the young man whom we met at the opening of this lesson, was advised by the last specialist he had consulted to drink nothing but pure mineral water so that he would be assured of getting all the minerals his system required and, also, to drink at least one pint of milk every day and to take his prescribed mineral supplements in order to maximize his calcium and other mineral intake.

In this day of known soil mineral deficiencies, should we supplement the mineral content of our foods in order to be sure that we receive a sufficiency of these important nutrients? Do herbs offer a panacea for all of mankind's ailments as many herbalists contend? After all, it is well known that mankind has historically used herbs since time immemorial and, therefore, *ipso facto*, they should be an important part of our armentarium so that our systems will be well fortified against possible "attacks" by germ, fungus and/or virus. In other words, through supplementation we can gird our loins, as it were, to do battle against a formidable foe.

Some scientists contend that cooked food is easier to digest than uncooked, that man has cooked his food for so long a time that his digestive organs have become adapted to eating cooked foods, that it is no longer possible for humankind to subsist totally on uncooked food, even though he may once have done so, that his digestive organs have changed over the centuries to accept cooked food and reject raw fruits and vegetable foods as indigestible. We know this is *not* true.

These "scientists" recommend mega-vitamin and mineral supplementation as a means of ensuring a more youthful resurgence of energy and higher level of health. Do we dare postulate the question, "Is vitamin dosing another gimmick, one perhaps that ensures an acceleration of energy outflow rather than the longed-for extender of youth?"

Are there certain commonly accepted but harmful practices we should all avoid if we would either restore a state of diminished health to a higher level or retain the good health we now have? We believe there are and, hopefully, we will learn some of these in this lesson. Natural hygienists contend that the very structure and function of the body, its physiological and biological methods and practices, its capabilities and limitations, dictate certain unchanging principles which should and, indeed, must dictate how and in what manner the human organism must be nourished to remain in superb health.

## **1.6 Unchanging Principles Govern Life**

Hygienists unequivocally hold that a general law under-girds life, one derived from physiology and biology and that we cannot escape the rule of law either in our eating or in our living, if we would retain our health. If we would escape the degenerative diseases that plague the vast majority of people, we must learn not only what we *should do* but also what we *must not* do. When the laws of life are ignored and possibly defied, due accounting will be required of us and, more often than not, such accounting will result in the rapid or more subtle erosion of health according to the inherited constitution and the extensiveness and intensiveness of the infractions of physiological and biological order.

In this lesson we will expand our knowledge in this respect. When we fully understand the truism that we, like all living things, are a part of the universe, one with all life and governed by exact laws, we will cease chasing after "cures," we will stop popping our pills and having recourse to vile substances; we will forego our stimulating habits and practices and start living hygienically, in accord with body design. As was said long ago by one Thomas Campanella, "The Laws of Nature proclaim themselves and are their own avenger." And let us proclaim with equal truth that the Laws of Nature, when obeyed, will reward us most magnificently with all the many faces of joy.

## **2. Vitamins**

### **2.1 A Statement**

In this lesson we will not concern ourselves with specific functions of particular vitamins, nor will we identify precise sources for obtaining this or that vitamin, nor with minimum daily requirements per se as set forth by governmental agencies, nor with similar data. There are any number of books and pamphlets setting forth such information and we refer our students to them. Our concern here will rather be centered on vitamins as a class and whether or not supplementation of the diet with man-made manufactured vitamins is advisable for health-seekers. We, of course, accept the fact that real vitamins are a necessary nutrient of life.

### **2.2 What Are Vitamins?**

Most people who take vitamins religiously have little or no real understanding of what vitamins are and what their function in the body is. Vitamins are not mysterious substances that hold the key to life and health in and of themselves as one might be led to believe by reading the popular literature on the subject.

### **2.3 A Very Profitable Business**

The selling of vitamins is a very profitable business, profits often being as high as ten times over cost. Increasing numbers of persons searching for better health "repair" are purchasing vitamins. The gross incomes of many proprietors of these outlets are well over the six figure dollar mark annually. Some physicians make a practice of selling vitamins directly to their patients also, making their purchases from large pharmaceutical houses.

### **2.4 As Members of a Group**

Real vitamins are simply one of a group of organic substances which are present in exceedingly small amounts in natural foodstuffs. They are essential to normal metabolism and, if they are in short supply, certain changes adverse to health can result.

These changes are generally cumulative in kind, not spectacular. They do not arise following a single failure to obtain a particular vitamin or group of vitamins but, to the contrary, adverse tissue changes and organ degeneration are, more often than not, the product of many years of poor management of SELF, including among many others, the failure to provide an adequate intake of vitamins from natural sources.

### **2.5 Need for Vitamins Grossly Exaggerated**

Vitamins are only one of a group of natural accessory food factors very important in the maintenance of health. They are taken into the system as an accessory factor whenever food is eaten, foods such as ripe luscious fruits, leafy green vegetables, and other delectable food packages which come from Nature's hand.

Our systemic need for vitamins has been grossly exaggerated by certain commercial interests and, as a result, there are numerous uninformed individuals who indiscriminately ply their bodies with as many as a hundred different supplements of one kind or another every single day, some even taking single vitamins in enormous amounts, in what are known as megavitamin doses.

Not too long ago we were counseling a woman who suffered from a rheumatic disorder which greatly curtailed her ability to get around. At our first meeting she spread out on the table an array of supplements, including a variety of vitamins, that was hard to believe. She took vitamins with her meals and in between meals, before going to bed and upon arising in the morning, all in doses many times greater than those recommended by the government. She said she had been taking these massive doses simply on the basis of what she had read in the popular magazines.

"For well over a year now, but I don't seem to be getting any better. The pain goes on and my muscles keep getting stiffer." And then came the plaintive cry we hear so often, "What can I do?"

## 2.6 The Problems Posed by Excess

We found it necessary to explain to our client that, as with overnutrition of any kind, when the body's need for any nutrient is exceeded, the system is called upon to dispose of the excess as best it can and, in the process of doing so, the liver and kidneys are overworked and the adaptive energy and other reserves of the body wasted, never to be retrieved. Once wasted, the life energy is gone, it cannot be recovered to any appreciable extent. This woman has wasted her precious energy in coping with *unnecessary* and *unusable* materials she had been constantly putting into her mouth. It was little wonder that her health had kept on its degenerating course.

## 2.7 Discovery and Chemistry of Vitamins

The term "vitamin" first appeared in the year 1912. So, vitamins are a comparative newcomer on the nutritional scene. They were so named by one Casimir Funk, the scientist who gave this name to the substance which he obtained from rice polishings while attempting to isolate the factor, the absence of which was believed by some investigators to be responsible for the condition known as beri-beri. The substance Funk obtained was a pure crystalline chemical to which he gave the name "Vitamine." We now call it Vitamin B1 or Thiamine.

The two parts of the word vitamin mean "life" and "amine." An amine is a substance derived from ammonia, the formula of which is  $\text{NH}_3$ , the N standing for nitrogen and H being the symbol for hydrogen. Ammonia therefore consists of one atom of nitrogen to three atoms of hydrogen, thus the formula  $\text{NH}_3$ . When one atom of hydrogen is replaced by a hydrocarbon or other radical, we have a primary amine, when two are replaced we have a secondary amine, and so on.

A primary amine might be  $\text{NH}_3\text{CH}_3$ . As you can see, here one hydrogen atom has been replaced by one  $\text{CH}_3$  grouping (a radical).

A secondary amine might be  $\text{NH}(\text{CH}_3)_2$ . Here, two hydrogen atoms have been replaced by two  $\text{CH}_3$  radicals. And soon.

This is the basic chemical structuring of a vitamin, some being more complex than others.

Since Funk's initial research, efforts to find and isolate these new and exciting substances have gone on ceaselessly and still continue today.

## 2.8 List of Isolated and/or Identified Vitamins

- Vitamin A
- Vitamin D - Ergosterol. Viosterol. Calciferol.
- Vitamin E - Tocopherol, D-alpha tocopherol, tocopheryl, dl-tocopherol
- Vitamin C - Ascorbic Acid. Cevitamin Acid.
- Vitamin P - The Bioflavonoids - Not true Vitamins

The B Vitamin Group:

- B1 - Thiamin. Thiamine Chloride. Thiamine HCl.
- B2 - Riboflavin. Vitamin G.
- B3 - Niacin (two chemical forms: nicotinic acid and nicotinamide, the latter also often called niacinamide; Niacin Amide).
- B6 - Pyridoxine. Pyridoxine HCl.
- B12 - Cobalamin. Cyanocobalamin. Also called the "Red Vitamin."
- Biotin - Vitamin H
- Choline - one of the "Lipotropic Factors."
- Folic Acid (also known as Folacin). Pteroylglutamic acid.
- Inositol
- PABA (Para-aminobenzoic Acid). Bx.
- Pantothenic Acid
- B13 - Orotic Acid
- B14 - A mix of Vitamin B10 and B11
- B15 (Pangamic acid) - Does not meet the criteria for a vitamin.
- B17 Amygdalin. Known as Laetrile. (Does not qualify as a vitamin.)
- Vitamin F - Essential fatty acids
- Vitamin K - Menadione
- Vitamin T - Sesame seed factor, unidentified
- Vitamin U - Vitamin-like factor found in some vegetables, cabbage, for example.

## 2.9 Grouping the Vitamins

Vitamins are organic chemical compounds which are normally divided for purposes of convenient identification into two groupings:

1. The Fat-Soluble Vitamins
2. The Water-Soluble Vitamins

Only the more familiar vitamins are so classified. They are grouped in this manner because they cannot be more readily classified because of their chemical similarity as can be done, for example, with the various kinds of carbohydrates which, as the student already knows, can be easily grouped as monosaccharides, disaccharides or polysaccharides according to the complexity of their molecules and the similarity of their chemical construction. This is not true of vitamins since they differ widely in their chemical make-up with no clear pattern emerging.

Some vitamins are proteins with very complex molecules while others seem to be simple amino acids. Many people consider vitamins to be food, but vitamins are really not food in and of themselves, but rather protein compound's or simple amino acids which assist the body at the cellular level to utilize and assimilate the food which is eaten and, in excess, they stimulate the metabolic process. Their main responsibility is to regulate body activity.

The body also has other helpers which also perform this same regulatory function—namely, the enzymes. No one is exactly sure just how enzymes go about their very important duties but we do know that thousands of chemical actions and interreactions which are all a part of the cellular scene depend upon enzymatic action. Without their presence, these metabolic functions simply could not take place. As we shall see later, without the presence of certain enzymes, many bodily processes in which vitamins play their own peculiar role would require such high temperatures that the body would literally burn up.

Thus, the vitamins assist the enzymes, too, in their catalytic work and, for this reason, are often called "Co-Enzymes." They assist both hormones and enzymes so their role might be compared with that of the nurse's aide who assists the registered nurse in caring for all the patients!

## **2.10 Vitamin-Enzyme-Hormone Synergism**

The secretions of the ductless glands, hormones, are the prime regulators of metabolic activity in addition to performing the very important task of instigating metabolic action. The hormones are normally referred to as instigators of metabolic action; that is they are primarily responsible for keeping metabolic activity going on. But, additionally, and most importantly, they also serve as regulators of metabolism, seeing to it that things do not get out of control—that we don't wear out the physiological clock, as it were, making things go too fast.

Thus we can see that vitamins and enzymes dually share in this major responsibility working in tandem, as it were, with the hormones. None can fully fulfill its responsibilities without the presence of the others. This is synergism at its best.

## **2.11 Vitamins Have Other Roles**

So far as is known, vitamins supply no energy or nutrient to the human body but simply make it possible for the system to appropriate the proteins, carbohydrates, fats and salts. We also know that they are absolutely essential to growth because they are required in cellular replication (division); they play an important part in the regeneration of cellular matter and in the overall maintenance of health. Some of them are probably involved in membrane maintenance, in the stimulation of brain action, cleansing of the peripheral capillary system, in blood clotting, and in a myriad number of other activities. Their total role will probably never be known.

## **2.12 The Fallacy of Vitamin Supplementation**

From the foregoing, it would appear logical to assume that the more vitamins we can take, the healthier we should become but, unfortunately, this is simply not true. We have a limited capacity to utilize and/or to store vitamins, as is true of food. When any substance, including vitamins, is introduced into the system in excess of present need, an unnecessary burden is immediately placed upon all the organs and systems. They cannot use the product. It is an obstructive influence in the body and therefore potentially harmful to it. The organic domain is placed in the position of having to cope with it in the least damaging manner.

The presence of any excess or foreign substance is immediately recognized. The danger-ahead alert is sent via the nervous transmitting mechanisms (the nervous system) to the control center in the brain where it is interpreted, evaluated and an appropriate response (instructions) sent out; or perhaps the alert may be relayed to a more locally placed substation (a plexus) for a sympathetic response.

If an obstructive foreign substance (for example, a vitamin overload due to dietary supplementation), cannot be stored or disposed of by temporarily or permanently "dumping" it somewhere in the body where it will not greatly interfere with normal systemic function but can be "tolerated," then the body will instigate other measures to get it out of the system as fast as possible.

The usual route for such exodus is via the kidneys and when the kidneys are thus called upon for emergency service, they must necessarily work overtime. Vitamins, when taken in excess of actual body need, are handled in exactly the same fashion as any other unnecessary impediment. In the case of vitamins, the easiest and quickest way to get rid of existing excess is to incorporate it in the urine and send it out of the body via the bladder, making the urine a very expensive secretion, indeed!

In order to accomplish the "dumping" or the rapid exodus of any foreign or excess material, vitamins or other, the body is stimulated by the nervous response and shifts into "high gear," stepping up the metabolic activity. The stimulation makes the vitamin-taker feel good, at least while he takes the vitamins, and it is for this reason that the need for this kind of stimulation can become habitual.

Why, you ask. It seems that a very delicate balance obtains among and between the secretions of the ductless glands, the hormones, the vitamins and the enzymes; especially with the millions of enzymes

which are directly concerned at the cellular level with the multitudinous activities comprising the life process. You see, once inside your body the vitamins take their proper place in a tremendously complicated scheme of life about which we actually know very little. They do not just work alone but they require other factors for them to be effective at all, factors like fats, minerals, hormones and so on. Only too soon the body becomes accustomed to their stimulating presence and when deprived of it, can sink to an unexpected and quickly felt lower level of well-being as attends all drug withdrawal.

We are only becoming more informed in this area of concern through microbiological studies. We really know very little about life within the cell. But what we do know strongly suggests that the indiscriminate taking of vitamins could and perhaps does disturb delicate internal nutritive balance resulting in metabolic confusion, a confusion which disrupts and diminishes efficiency of performance. Health is reduced commensurate to the imbalance.

Some vitamins, like the enzymes, are found in just about every living cell, plant or animal. Not all Vitamins however, are required by all animals but it does seem to be a requirement of life that the vitamins required by a particular kind of organism must be present at all times, each to play its own specific role as to time and place within that organic community. This is true, also, of man but, as we have noted, the vitamin role is secondary rather than primary, that of assistant, not instigator.

### **2.13 Human Guinea Pigs**

Vast realms of the human life motif are yet to be explored and resolved in finality. Millions of people who are presently taking vitamins are willing guinea pigs in a vast experiment, the results of which are, by the measure of things, completely unknown and unpredictable in the absence of long-term and precise evidence.

Those persons who enthusiastically promote mega-dosing of vitamins do so on the basis of evidence that is often misleading because it is insufficient on many grounds and often misinterpreted. For example, hamsters which developed lung cancer due, in part, to exposure to smog and cigarette smoke were given Vitamin A and, according to the researchers, the development of cancers was halted. These results were interpreted to mean that dosing with Vitamin A helped to prevent the cancers from arising.

Since it takes years of body mismanagement and a multitudinous number of physiological errors to produce, as a final conclusion of the pathological process, the condition of true cancer, this was certainly a simplistic assumption to make, especially in view of the fact that, to the present at least, there are no known methods of accurately determining exactly what else is going on in the recesses of an experimental subject. It may well be that the drugging effect of suppressing symptoms may be operational within cells to be stimulated at a later date to an unhealthy derangement of cellular growth. Vaccinations prevent symptoms from arising through the toxicosis and unhealthful practices continue. Disease continues its evolutionary ways and manifests itself years later, often in more horrendous ways.

It is said that autopsies reveal that vitamin deficiencies are widespread, not only in other parts of the world; but here in America in the face of an abundance of readily available food. This is the rationale which is used to promote vitamin dosing. Little or no attempt is made to inform the public as to the realities of organic existence, to ascertain what errors are being made in eating and living that produce vitamin deficiencies in the first instance. Instead, the populace is lulled into believing that they can continue to eat *a la* their television instructions, to eat "junk" food, in fact to disobey all natural organic law and, in spite of their indiscretions, maintain a lasting health. Manifestly, this is impossible. They are being stimulated, propped up and goaded into a false sense of security, instead of being encouraged to partake of nature's grand packages which contain all the vitamins man could ever need or want.

### **2.14 The Living Plant as Provider**

The living plant is the only organism which can synthesize vitamins, though animals create some vitamins too. This fact means, in effect, that all animals are dependent upon the vegetable kingdom for

their vitamins. It is true that some animals can take the immediate predecessor, the precursor of the vitamin, the provitamin, and from it complete the synthesis of the vitamin itself as, for example, man can take the carotene provided by the carrot and also in other vegetables and by a series of changes, chemical in nature, convert it into Vitamin A. To a limited extent, man is also capable of storing up vitamins in his liver and elsewhere within his body, these being included among his adaptive reserves, held in readiness for times of unusual need.

Another point of interest in this discussion is the fact that plants which have the highest mineral content also have a high content of vitamins and that the particular part of the plant which is richest in minerals is also richest in vitamins. In other words, it would appear that nature is telling us that the life processes which favor the appropriation of minerals by the plant also favor the synthesis of vitamins and that perhaps because all of nature is so symbiotically intertwined that the carefully proportionated relationships displayed by plants designed for man's consumption might also be most favorable to body processes in the human who eats of the plant.

The darker the color of the plant, the higher its vitamin and mineral content. When leaves of plants are exposed to many days of suitable sunshine, they are more abundantly endowed both with vitamins and minerals. This fact seems to tell us something: namely, that insofar as both plant and animal existence is concerned, there is a relationship existing between the vitamins and minerals, a precise balance in each plant and, indeed, in each part of the plant. It would appear reasonable to assume that, if we desire a maximum vitamin-mineral intake, we should eat of those foods that are well exposed to the sun; we should choose foods which grow above the ground for a well balanced nutrient pool and, to conserve body energy, we should concentrate on those foods that not only contain valuable nutrients but are also easy to digest and do not possess known irritants. A plant having the highest vitamin value may not necessarily be good for man to eat. A single example should suffice to illustrate this point: hot red chili peppers (raw) per 100 grams contain 21,600 units of Vitamin A as compared to a luscious ripe peach of similar weight which yields only 1,330 units.

Vitamins are found in all vegetables and fruits that serve as food for humankind and in adequate quantities. The amounts are small by our way of thinking. But nature seldom errs, we can reasonably infer from this fact that the human body's systemic need for vitamins is probably "very small." This concept, of course, has been borne out by considerable research using radioactive additives in cell studies, these being traced in their progress and utilization by means of high-powered electronic microscopes. Additionally, the theory seems reasonable also by virtue of the fact that the role played by vitamins in the living body, while essential, is still limited to that of being regulators of activity and also because they share this responsibility with the hormones.

We, the authors, have not used manmade vitamins for many years now but our health continues to improve and our energy flow does not seem to be disrupted by our abstention. An overkill of any single nutrient factor can destroy the delicate relationship among and between all nutrients and, it might well be disruptive of endocrine performance.

## **2.15 Overkill**

Let us postulate what overkill may do. We have established the symbiotic companion action of hormones, enzymes and vitamins. Whenever hormones are not present, the production is shut off. This is known as hormonal feedback. The danger of disturbing hormonal feedback is always present when vitamins are introduced in excess of systemic need because of the stimulating effect they are known to have.

There is a precise relationship among and between the various endocrine glands under the planned instigative control of the hypothalamus-pituitary twin glands. An intelligent dictatorship determines the outflow of hormonal secretion and the stoppage of same according to the need to instigate some kind of action within the body (to use a common example, flight in time of danger) or to stop an operation in progress (for example, insulin production). The possibility arises that the presence of an excess of

vitamin input which also serves, we must remember, as a regulator could disrupt the precise management of metabolic activity and perhaps even overstimulate, producing undesirable effects, the so-called side-effects of drugs which are, after all, regular effects, always present but not always discernable. At the very least, any excess input can accelerate the biological clock.

As we have said many times, our knowledge of the biochemical goings-on within the human body are still in the pre-kindergarten stage and we place ourselves in jeopardy when we start tinkering with the body's finely tuned processes, when we pre-judge an unknown systemic need and ingest via the oral cavity or inject into the blood stream extraneous manmade substances of doubtful value, no matter if they are touted as being obtained from a natural source, they are not natural in the real sense.

In the light of our present lack of any accurate knowledge as to the exact dosages required (the government-recommended RDA's are, at best, an over-liberal (and over-lethal) guesstimate), the problem always remains as to exact need human organism can determine this with any degree of accuracy.

While minimum daily requirements for individual vitamins have been put forth, there has, to date, been no absolute test to evaluate relative vitamin needs; that is, we do not as yet have a reliable understanding of the proper proportionate values of one vitamin to another or of each to all and, again, to the hormones with which they share certain responsibilities. Surely, these values must change from, individual to individual according to metabolic efficiency. It appears all but impossible to predetermine the exact need of any one individual, let alone people in general, this certainly being a variable as metabolic circumstances fluctuate and change. Also, another point deserving our attention is that manufacturers of vitamins necessarily must use chemically pure vitamins for the most part. If they used only naturally derived vitamins, their pills would be too large for us to swallow. Natural foods contain too small amounts of vitamins to formulate heavy drugs. Additionally, they find it necessary to add a "carrier" to make their products more acceptable to the palate and to bring their product up to an exact pre-determined standard. We have no way of knowing the precise effect these chemical carriers may have on the system. It seems more in keeping with nature's plan for living to take vitamins as contained in nature's offerings where they are in organic context.

Since we know that the human body is a finely-tuned masterpiece and that simple maladjustments often present serious health hazards, this matter of vitamin proportions and relationships, as well as further consideration of carriers, could well be more important than has yet been realized. People have been dosing themselves and their children now for a considerable time with multitudinous kinds of vitamins and vitamin combinations, often in extremely large doses. If vitamins were the panacea to all health problems as they are so often represented to be, surely during the last half century we should have witnessed a phenomenal improvement in the health of the people but, unfortunately, the contrary appears to be true.

Arnold Fox, M.D., assistant professor of medicine at the University of California at Irvine Medical School and a lecturer at the Charles Drew Medical School, stated in an article published in *Let's Live Magazine* (June 1982) that he is now "treating the 20- and 30-year old children of my patients. These children are, on the average, as sick as their 50, 60 and 70-year-old parents..." To be sure, the deterioration in the health status of these children has been brought about by many factors but it is certain that the taking of multiple doses of vitamins, numerous vaccinations and other well publicized "preventive" measures has not prevented systemic deterioration; instead, it may well have accelerated it.

It would appear obvious to any discerning person that the answer to rapidly deteriorating health does not lie in taking pills, potions or injections. Most of the recommendations for supplementary vitamin usage have come about through experimentation on animals in a controlled environment situation. These experiments show results for a particular species of animal under the controlled circumstances, not as they might be in the wild.

Furthermore, the species of animal on which the tests were made may or may not bear great biological relationship to humankind and certainly the controls operational in a laboratory situation can bear little

relationship, if any, to the stress-wracked frenzied, emotion-charged life of the average person today whose metabolic activity is being constantly monitored by the endocrine gland and nervous systems.

Additionally, the experiments, by and large, have been of too short a duration to be valid. Being scientific researchers ourselves, we can say that "they" assume too much on too little evidence. It has long been known that it takes four or five generations to evaluate a dietary change. Consequently, the tests, as Herbert M. Shelton so well points out, are applicable only to the animal in question (under precise circumstances and conditions, we might add) and are not "strictly and broadly applicable to man." They might not even be strictly and broadly applicable to the *same* animal under other circumstances.

Sylvester Graham in his *Lectures* pointed out that there is similarity of function and application of principles throughout the animal kingdom, but that there are also fundamental differences from species to species. These fundamental differences make all animal experimentation suspect. The assumption of an accurate response may not always be confirmed in the revealing light of subsequent reality.

Experiments can be designed in such a way that they will produce a desired or hoped-for result. Much of the research presently being conducted is subsidized research, paid for either by government, organized groups, or commercial companies having a vested interest in certain results. Persons receiving subsidized grants, many involving enormous sums, might possibly be inclined to slant the results of their research, even without their being consciously aware of their thrust, in order to please their sponsors and keep the money bank open.

## 2.16 The R.D.A.'s

The average man weighing 160 pounds contains within his entire body just about 1/4 ounce of vitamins. Now it takes approximately 28 grams to equal one ounce, so this means that, if we add up all the many different kinds of vitamins in the average man's entire body, we would have only about 7 grams total, including all the reserve supplies, those that are stored up in the tissues and organs for emergency purposes, particularly in the liver and kidneys.

The R.D.A.'s (The Recommended Daily Allowances) are about double (in some cases even more) the estimated minimum requirements, which many scientists admit are not easily determined. In other words, these figures are no more than guesstimates. In fact, some scientists contend that, while extra vitamins may be needed to correct certain deficiency diseases in extreme circumstances, normal persons do not require supplementation since a good diet provides amply for all such needs.

Certainly their ideas as to what constitutes a "good" diet may differ from our own, but even so, the Food and Nutrition Board, a division of the National Research Council (organized by the National Academy of Sciences) postulates that the average adult eating a well-balanced (comprised of the appropriate amounts from each of the four basic food groups) diet will receive 7,500 International Units of Vitamin A. The R.D.A. for Vitamin A is only 5,000 units.

There is no need whatever for any person on a Hygienic diet to harken to the siren call of the paid hawkers of commercial wares—synthetic vitamins. Nature has provided well for all of us. Many millions of people lived in health for centuries before Dr. King concluded his monumental experiments at the University of Pittsburgh and isolated Vitamin C from lemons. Any *real* student of health knows that the chemist and/or the manufacturer cannot put life and health into a bottle of pills. Neither can the life force resident within a plant be extracted and compressed into a capsule and still be viable.

If you eat fresh uncooked fruits and a limited amount of fresh leafy vegetables, a few nuts and edible seeds, you will take in *many times* the recommended amounts, not in synthetic isolated vitamins to stimulate and accelerate organic response beyond its norm, but rather in desirable metabolically correct combinations with other nutrients, nature's bio-chemical partners.

## 2.17 Vitamins and "Cures"

There are many so-called "cures" attributed to vitamin "therapy," just as there are many so-called "cures" attributed to this or that drug. To say that vitamins can "cure" an existing malfunctioning within a sick body is to admit ignorance of the nature of disease and is an admission of commonality with the drugging practices of the vast majority of medical practitioners.

The giving of vitamins "therapeutically" or the introduction of drugs orally or by injection in the hope of favorably influencing the progress of a certain disease is a serious error because, in reality, we do not cure but simply suppress the curative actions already in progress within the system, these having been initiated by the organism itself. The suppression of the symptoms is what is normally accepted as a "cure," but, unfortunately, the cure represents only a temporary surcease until utility is recovered.

Whenever any unwanted or foreign material is thrust into the system, all vital powers of the organism that can possibly be spared from vital processes must be employed in rendering it harmless. This effort, when continued for any length of time, actually results in changing an acute crisis of healing, one that is usually of a comparatively short duration, into a chronic disease which the body will conduct unceasingly. Chronic problems often result in acute crises that can even bring an end to life itself.

Drugs have been used for thousands of years of man's existence to relieve hurts and to "cure" diseases. Man has a tendency to hold fast to his habits even though they be destructive of his very life and it is this tendency that causes man to seek "cures" rather than to determine the root of his troubles and then change, discard, modify or remove that which tends to destroy him.

We are just now beginning to understand the dangers inherent in all drugging. And, make no mistake, the vitamins of commerce act in exactly the same manner as drugs. *They occasion body defensive actions.* The toll from iatrogenic diseases (drug-related) has gone beyond the point of toleration by an enlightened public.

The toll exacted from drugs often rears its ugly head in countless unnecessary deaths and in the form of mutations in infants which must be destroyed in utero at birth and relegated to the garbage heap; in cancerous tumors which come in second and third generations; as well as in numerous less distressful symptoms soon forgotten. What the effect of our present vitamin stimulation craze may yet prove to be is a total unknown. We have no way of following successive generations of long-living humans to make a liable assessment.

Vitamins are drugs. Using vitamins is similar to drugging. The body reacts to vitamins just as it does to any harmful substance: it goes into defensive action. The pills can do nothing except perhaps enter into a chemical action of some kind. We should remember that building health is harmonious body effort, not a defensive action. Life is either "cumulative or dissipative, never static." Simply taking this vitamin or that vitamin pill will never, by any stretch of the imagination, get at the root cause or causes of a deranged body. It will never render the thickened viscous fluids of the hypertensive patient (one who has high blood pressure) pure and free-flowing; it will never heal a damaged heart, gallbladder or spleen.

The system, of course, learns to tolerate the vitamins, and the stimulation they provide often makes the person taking them feel "good;" but the good they give wears a false face, a facade that cheats, since it is the result of excitation, not health. Unfortunately, an excitation is gained at the expense of loss of vital power, power that, once lost, can never again be wholly retrieved. Only too soon, the false face fades, revealing the cruel reality of premature aging and its companion, ugly disease.

## 2.18 Life Science Is a Better Way

Life Science is a better way. Any person who desires the full joy of abundant health must either grow his own produce or have access to fresh fruit and vegetables, preferably organically grown, either by himself or available to him freshly picked from another source. Synthetic vitamins are divorced from their natural carriers and cannot be depended upon to build health. Life Scientists put their trust in

Nature's ways. Nature gives us a guarantee!

We can save on other things, if need be, but if we desire the best of health, we should have access to and use only the best quality of food. And, even better, we should plant our own garden of vegetables and a variety of fruit and nut trees. *We should become activists and encourage the public to plant fruit and nut trees to adorn our highways, parks and roads.* As Otto Carque said, "to provide food for generations to come."

As Life Scientists, we should feast on the fruits of our labor, harvesting beautiful vegetables, fruits and nuts at the peak of perfection, ready not only for our gustatory enjoyment and delight but also to provide amply the wherewithal for living always in a state of superb health, without our ever having to rely on synthetic man-made products, the effect of which we have no fool-proof way of evaluating. We should, above all, emphasize in our diet those most perfect of all foods, the luscious ripe fruits, fruits endowed with all the nutrients we could ever require to sustain us in perfect health throughout a lifetime of sickness-free living, always retaining a keen awareness of the universe around us and keeping in tune with the realities of life until the time comes when the life force gently slips away.

[Home](#) > [Lesson 39 - Food Supplements](#) > 3. Minerals

## 3. Minerals

### 3.1 The Primary Role of Minerals

In spite of the fact that the role played by minerals in human ecology is a primary one, mineral nutrition is a relatively new field of interest. In 1904, Dr. Harvey W. Wiley wrote to Otto Carque, a celebrated biochemist of that era, as follows: "I regret to say that no one in this country has undertaken a complete analysis of all of the mineral constituents of foods." A German physician named Dr. H. Lahmann was perhaps the first scientist to direct his attention to the role played by food minerals in human nutrition. Dr. Lahmann wrote extensively on the subject in his book, "Natural Hygiene." He was rapidly followed in his work by Carque whose outstanding book, "Rational Diet," was printed in 1923 in this country and is still available in reprints.

Dr. Herbert M. Shelton has called minerals the real "building blocks" of the body. They are basic to the construction of bone, tissue, nerves and muscles; indeed, of every part of the body. Additionally, they are required to sustain every function of the organism. Without minerals we couldn't move or think. They constitute our main adaptive reserves, they provide us with the means to withstand the common stresses of the day and unanticipated trauma that may come. It would be impossible to recite their manifold functions and even so, there are, undoubtedly, functions innumerable which remain hidden in the closed recesses of the human labyrinth.

Even though minerals are manifestly of great importance to life, they are probably the most neglected area of concern in the scientific community, although in recent years more and more attention is being directed to them and to the role they play in the continuing life process. Dr. Roger J. Williams, a biochemist, in his book "Nutrition Against Disease," points out to his readers that the thesis of the work is "that the nutritional micro-environment of our body cells is crucially important to our health and deficiencies in this environment constitute a major cause of disease." The opening chapter in this work is well worth the student's attention. It presents an excellent *critique* of present medical thinking and training and the extent to which it is circumscribed by the standardization imposed upon physicians by the American Medical Association. At one point Dr. Williams points out that, "When science becomes orthodoxy, it ceases to be science." In his emphasis on the "Nutritional Chain of Life," Dr. Williams

simply stresses what should be obvious to all: the cellular need for the entire spectrum of nutrients, known and unknown, including the primary actors in the drama of life, organic minerals.

### **3.2 Indoctrination of the Public**

Because of the growing interest in the field of nutrition by a public disillusioned with the drug, cut, sew and stitch mentality of modern medical practice (as much as one-third being so disillusioned), certain commercial interests have issued a siren call extolling the virtues of adding minerals to a multi-vitamin intake. Such advice is forthcoming on the basis largely of animal experimentation which, as we have already observed, is usually conducted under strictly controlled circumstances on biologically unrelated test animals whose life spans are relatively short when compared to that of man. It is on the basis of this kind of encapsulated research that the public is being wooed to supplement its food intake with a varied assortment of bottled vitamins and minerals even though the experiments are obviously of too short a duration to be worthy of serious consideration.

### **3.3 Minerals for Humankind**

The human body must obtain its minerals in the form of organic salts which are present in all foods. But not all plants are fit for human food. Food is any substance which can be used by the organism, in this case man, to make blood, formulate secretions, construct bones and ligaments and build tissues and nerves without adding anything that might prove overstimulating, exciting, irritating to the cells or destructive thereof, or obstructive to function.

Man eats his food in the form of fruits and certain vegetables which contain the necessary organic salts and then, by the sequential processes of digestion, absorption, transportation and cellular assimilation is able to reorganize them into his own organic substance suitable for growth, repair, healing and for whatever function may be in order to meet the precise needs of the moment. These complex processes are concluded with drainage whereby the metabolic waste byproducts are removed and returned to their point of origin, the soil. All of those complex processes represent the internal cycles of life, which when total and kept in proper balance are capable of maintaining cellular (and thus body) health theoretically for an indefinite period of time.

### **3.4 The Bio-Ecosystems**

All life is divided into three biologically distinct groupings: the Animal Kingdom, the Plant Kingdom and that "in-between" grouping known as the Saprophytes which, properly, do not belong in either of the two familiar Kingdoms.

The Saprophytes take the organic refuse of the world, dead plants and animals made up of organic molecules and, by the process of metabolism, disorganize it into simpler inorganic mineral elements which are then yielded up again to the soil, thereby becoming available, in an aqueous solution, to the plant where it is processed, reorganized once again into organic molecules suitable for the maintenance of the health of the plant. Suitable warmth, mineralized water and a friendly environment are essential to the efficient performance of this part of the plant cycle.

The inorganic minerals derived from decaying dead organic life, both plant and animal, thus become once again endowed with the life element, they become once again a part of a living structure, in this case of a plant, and are assigned various positions and duties within the plant organic community. Every plant has its own special design and structure, its own peculiar assortment of organized organic molecules.

Roots have their own exact array within the organized mineral community, leaves another, the fruits still another and so on. Seeds contain the force of life, the ability to reproduce. Together, all the parts of the plant represent the food bank of all the world's living organisms, from the largest to the smallest, both

plant and animal.

In the earth's carefully programmed ecological sequence, animals are not designed to utilize inorganic minerals. Nor do they have the ability to utilize them in the life processes of building, repairing, healing, replication or in any function of any kind. To the contrary, animals are able to use only organic minerals as food and each species has food which is set apart for its use. Grains keep birds in, perfect health. Each morning here at the ranch we feed the many species of birds that live here: red-breasted finches and the desert owls of little size and haunting cry. They get plump and fat on our seeds and on native plants.

Man, not being a bird and lacking both a beak and a craw, cannot obtain adequate nourishment from grains (seeds). A turkey has a large gizzard and can process and then utilize enormous amounts of seeds, including nuts and the hard shells thereof. Man, on the other hand, is structurally designed to eat abundantly of ripe fruits, plus a few leafy green vegetables and perhaps some few nuts and edible seeds. Such food is suitable for humankind and all these foods are well supplied with all the minerals required to sustain him in superb health.

### **3.5 Inorganic Salts and Man**

Inorganic minerals will be rejected by the human body and, if they cannot be, removed from the body in some way, will remain in the fluids or be deposited as a precipitate wherever convenient, thereby proving to be an impediment to efficient function. Common table salt is such an inorganic salt.

Potassium salts are sometimes prescribed for heart patients, to raise the potassium level of the blood. A temporary elevation is often obtained but, upon discontinuance of the potassium pill, the level soon falls again. Last year we had a dramatic example of the folly of taking inorganic potassium. A client came to us with a potassium blood reading of 2.0, dangerously low (5 being optimum). She had taken an inorganic potassium supplement for many months but, whenever the medication was suspended, her potassium level rapidly fell. At the time she first came to us, she was fainting six and seven times a day. She was fed properly, mainly on fruits, leafy green vegetables, plus a few nuts and an occasional baked potato (not necessary but enjoyed by this particular client) and, within a very few weeks, her potassium level rose to 4.5 and has remained there ever since without benefit of any medication of any kind. She no longer faints and has shown a remarkable resurgence of energy.

If a sufficient amount of inorganic material is taken into the system, it may settle out adding to the viscosity, the thickness, of the fluids to such an extent that, in time, the body will simply have to deposit the "sludge" wherever convenient, in arteries, in joints, around nerve synapses, in muscles causing an imbalance in the solid-fluid ratio, with a gradual stiffening and rigidity of muscles and brittleness of the bones taking place.

Table salt is inorganic. If we add table salt to our food as a condiment and then ingest that food, we may find it to be highly toxic and destructive, especially of nerve tissue.

However, as, an organic component of a healthful food such as Romaine lettuce, produced for our sustenance by the combined efforts of bacteria, soil, air, sun and the plant itself, it will be put to good use within our body. For example, organic salt could be united with free-floating acid radicals which, if left alone to do their mischief, could tear the tissues apart but, when united with sodium, contained in the food salt, are simply eliminated from the body or perhaps just rendered harmless. The salt contained in food, being an organic salt, can be used. It can help keep the body fluids clean and pure. It also forms an important component of many body secretions, the tears and gastric juices among others.

Suffice it to say that to live we require a wide variety of minerals for all kinds of purposes. We require them for all the vital processes but we must remember that the body will reject inorganic salts because it has no mechanism to use them. Not that human design is faulty. It is just that a better arrangement has been made.

Nature has developed so that the human body depends upon only naturally chelated minerals, minerals

organically organized within living food molecules. It will reject the inorganic molecules because they are unusable. They contain no life. Food molecules, and especially plant food molecules, have incorporated within their complex structures the very essence of life. Man, having his own niche in the bio-ecosystems, is required to eat of the foods specifically adapted to his needs.

### **3.6 Chelated Minerals**

Laboratory-synthesized chelated minerals have become a big thing in recent years, their "virtues" being extolled in just about every popular health magazine on the market today. Chelated minerals are minerals that have been bound to or bonded with amino acids or to a more complex protein molecule. The idea seems to encourage people to "live symptom-free, but to keep the disease." The word is that if an individual will supplement his faulty diet with man-made chelated minerals, he will be free of his annoying symptoms.

### **3.7 Deficiencies and the Fallacy of Therapy by Supplementation**

Hair analyses are routinely made to detect mineral "deficiencies," as are blood readings. Unfortunately, perhaps, neither the hair nor blood is static. Their composition is always in a state of flux. But, be that as it may, many such "deficiencies" are attributed to poor digestion which, in turn, is simplistically ascribed to a lack of sufficient hydrochloric acid in the stomach. When this latter is suspected, it is the modern practice to perform the Heidelberg Gastric Analysis, a means of determining how much acid is secreted in the stomach via evaluation of radio signals sent out from a small capsule which has been swallowed, these radio signals being recorded by a special sensing device contained in a belt wrapped around the abdomen. In the event that a deficiency is recorded, the common practice is to provide in a little capsule the missing amount of hydrochloric acid. This "therapy" is intended to improve the digestion of protein and, thus, in due course, the mineral availability to the body. To ensure that the patient secures an adequate mineral intake in the interim, he continues to pop his chelated pills.

The basic fallacy of this type of "therapy" is that a lack of sufficient hydrochloric acid in the stomach indicates a deterioration in the health of the stomach acid-producing glands, these having been enervated by multiple errors in eating and living. As a result they may be burdened down with catarrh and be incapable of efficient production. Not only are the stomach glands affected by enervation but the entire system suffers. When any part of the body is tired, overburdened with toxic waste, efficiency of function is lowered.

### **3.8 A Better Way**

Hydrochloric acid capsules and chelated pills are not usable. They further cripple the body. Swallowing acid and popping pills is anti-health. The better way is to begin to cleanse the body, to get rid of the morbid wastes, to disorganize and remove the fat, to autolyze the cysts and the tumors and then to rebuild a healthier body, a superbly functioning organism, using all the fundamental requisites of organic existence. When this has once been accomplished, the symptoms will long since have departed, the blood and fluids will no longer be deranged or scant in supply, and they will be abundant and free-flowing, pure, and will run in their channels carrying mineral and other nutrients to service the needs of the cells.

### **3.9 The Law of Economy**

The Law of Economy states that where there is no demand for the production of a product (secretion, etc.), the body will not produce said product. If supplements are substituted for a product which is normally the result of a life process within the body, the time will soon come when the supplemented individual will become supplement-dependent, no longer able to manufacture the product so vital to his life. Without the supplement, his health will rapidly deteriorate. No "cure" has been affected, therefore

the lack will reassert itself.

When supplements are taken, the body is and will continue to be stimulated while the dosing continues. Supplement-taking cripples the system's powers of synthesis while the internal deterioration proceeds unabated. The process can be somewhat compared to the addiction that results when so-called "hard" drugs become a way of life. After a time, the individual more often than not finds that he must have recourse to an increased mineral intake in order to obtain the same feeling of well-being. But dosing, of course, has its limits since no healing has taken place.

### **3.10 Imbalances Within The Body**

Another point illustrates how futile it is to dose the body with this, that or the other mineral pill, chelated or not, and that is the fact that the human being must have all the nutrients present as and when required but, more than that, it must have them in their proper synergistic organization, proportions, if you will, one to another and each to all. The body will simply not put up with imbalances of any kind. In fact, when an imbalance exists, the body is in trouble and it will let us know by one method or another, by this symptom or that.

When an excess (or a deficiency) of any one material (or other nutrient) exists, an imbalance is present. Such an imbalance may cause the nutrient in question, mineral or other, to be worthless or, what is even worse, *it may prove to be a handicap to the proper utilization of all the other nutrients!* This is the Law of the Minimum.

Minerals are required by the living system; vitamins and enzymes are required, all the nutrients are essential to support the life systems but they must be present in a balanced synergized organic context as contained in the various food packages designed for man's use or they are worthless. Not only worthless, in and of themselves, but the imbalance created because the system cannot fully utilize isolated man-made minerals, chelated or not, reduces the effectiveness of all of the other nutrients, including perhaps even the organic minerals that are present in the dietary intake perhaps by as much as one-half and, if other deleterious factors are also present, possibly even more.

### **3.11 Selenium—To Illustrate a Point**

Selenium is a mineral that has come into prominence especially since the publication of *Selenium, As Food and Medicine* written by Dr. Richard Passwater, Ph.D., and published by Keats Publishing, Inc.

Dr. Passwater relates how important selenium is in maintaining health. The inference is certainly given that adding a little selenium to the diet may just help prevent a person's coming down with serious diseases. Following the publicity on the attributes of selenium, health food stores were invaded by persons eager to escape all the ills of the world's sick simply by adding a little pill containing this trace mineral.

Selenium is now included in most multivitamin and multimineral supplements. Oddly enough nothing is said about selenium's toxicity as added to supplements in an inorganic state. And even more, little is said about how the roots of certain plants, like the many fruit trees and the alfalfa plants, have roots which penetrate down through the surface soil deep into the sub-soil where they seek out and take up dissolved minerals of all kinds, gross and trace, these to be reorganized into plant substance to sustain the plant's specific needs. When man eats the fruit of such plants or parts thereof which are adapted to his body design, he receives all the minerals he can use, including the trace mineral selenium.

Fruits, the product of trees and vines, are the best of all foods just because their root systems are far-reaching and deep-searching. When fruits are formulated they contain within their rich goodness, all that man requires to live in health. Fed by the soil and air, they are man's finest food. When vegetables and a limited amount of nuts or edible seeds are also occasionally eaten, fruits will amply fulfill man's nutrient needs.

### 3.12 Minerals as a Nutrient

As we have previously noted, minerals are one of a group of nutrients. They are a part of every cell, tissue, organ and system of the body. They are especially concentrated in the bones, teeth, hair and nails. Without minerals, the alkalinity of the blood and other fluids of the body would be in extreme jeopardy because a correct mineral presence is required not only to sustain this alkalinity but also the viscosity (the stickiness, fluidity) and the salinity (saltiness) of all systemic fluids.

Minerals serve to detoxify the system whenever solid wastes threaten it. Therefore, whenever the human organism has a full complement of minerals, all readily available at the required time, it is protected against decay and rot. The proper concentration of mineral salts in the interstitial fluids keeps cellular membranes from bursting and spilling forth cellular contents. The proper proportion of mineral to mineral keeps the plasma membranes and cell walls intact with full selective power, the ability to accept or reject nutritive material as it passes by in smorgasbord style, offered up by the fluids as they journey on their course to every cell within the organic domain. These membranes also retain the ability to pass all obstructive debris which by its presence could disrupt cellular activity through and out of the cell.

Let us briefly explore another aspect of mineral balance. We have already pointed out that the blood and other fluids must keep a rather carefully prescribed quota of minerals at all times to maintain rather narrow parameters of pH (alkalinity). If the pH varies even minutely, sickness and even death can follow, and quite rapidly. In order to keep the pH stable, the homeostatic mechanisms of the body will take from those organs which are adequately provided with the minerals the system requires to perform specific duties and to take whatever amount is needed to continue the life process. The body makes the best use of its resources.

The mineral selected most often is calcium, this being in time of grave need, rudely obtained from the teeth (producing caries) bones (leading to sponging, osteoporosis). That mineral deficiencies are widespread is evidenced by the fact that over 99 percent of Americans have one or more dental caries and most persons over the age of 50 give evidence of osteoporosis. Taking calcium supplements which are inorganic cannot solve this problem. Rather, supplements may lead to faulty systemic managements, not only of calcium but also of other minerals according to the Law of the Minimum, demonstrating again how poorly the body can tolerate imbalances of any kind.

[Home](#) > [Lesson 39 - Food Supplements](#) > 4. Enzymes

## 4. Enzymes

### 4.1 A Question Answered

"Wouldn't it be wonderful if our scientists could come up with a substance which could assure digestion of our foods, clean our dirty sores, reduce inflammations, promote healing, liquefy the thick mucous discharges emanating from our many diverse serous and other membranes within the body cavity; in short, work all manner of miracles?" Well, they haven't, but Nature has! In fact, Nature has produced a whole family of such miracle workers and they are known as enzymes.

The human organism contains countless millions of enzymes. They are contained in the food we eat and in every cell of the body. Enzymes are very specialized organic compounds of polymers of amino acids. A polymer is a larger molecule or compound formed by the union of two or more smaller identical molecules. Enzymes are formulated when two or more identical amino acids are united in a chemical union.

Polymers are never found in the inorganic world. Therefore, enzymes are found only in living plants and animals. They are proteinaceous catalysts of biological activities. Since this statement is quite a mouthful, let us probe a little further to get a greater understanding of the specific role played by enzymes.

## 4.2 A Catalyst

The word catalyst is defined in the Thorndyke-Barnhart Advanced Junior Dictionary as "a substance that causes catalysis" with catalysis then being interpreted to mean "the causing or speeding up of a chemical reaction by the presence of a substance that itself remains practically unchanged," this last in our frame of reference referring, of course, to an enzyme.

The New American Encyclopedia (1939 Revised Edition) defines catalysis as a "chemical process by which the reaction of substances is quickened by an added substance which does not itself undergo a change. The added substance is called a catalytic agent or a catalyst. An example is platinum, the catalyst used in mfg. sulphuric acid."

## 4.3 Enzymes as Catalysts

Enzymes serve as catalysts to metabolic activity. They act to assist the speed of the many chemical actions and reactions involved in the metabolic process and also help these activities to be brought to a successful conclusion. As catalysts, enzymes are capable of increasing the rate and effectiveness of a reaction without being consumed in the process.

Many of the processes which go on in the human body at normal temperatures would require in a laboratory situation hundreds and even perhaps thousands of degrees of temperature and perhaps even the presence of a strong violent reagent for their accomplishment. These same reactions are accomplished by means of the enzymatic presence almost instantaneously in the calm peaceful environment of a healthy body.

## 4.4 Classifying Enzymes

Enzymes come in many sizes and vary as to their specific duties. At present over 700 different enzymes have been identified but so many millions of these miracle workers are known to exist that they have simply been grouped in three general categories, as follows:

1. hydrolytic (water-absorbing);
2. oxidizing (uniting with oxygen to supply heat and/or energy; as in a combustion);
3. Reducing (subtracting from a particular complex molecule certain elements, groups of elements or electrical charge).

These names are applied according to the type of process the enzymes control.

Individual enzymes are named by adding "ase" to the name of the substance on which they work, scientifically referred to as the substrate as, for example, the starch-digesting enzyme ptyalin or amylase. Trypsin is sometimes referred to as Trypsinogenase or proteinase because it assists in the resolution of protein (splitting the complex protein molecule into smaller chemical units or molecules). Lactase assists in the resolution of lactose, or milk sugar. And so on.

## 4.5 Enzyme Activation

Most enzymes actually exist in an inactive form until such time as their catalytic talents are called upon by the organisms. It is interesting in light of the fact that many people are taking enzymes regularly as supplements to realize that, in order to initiate the action by an enzyme, that is, to activate it, some metal ion (an electrically charged particle) or some simpler organic molecule or co-enzyme(s) must also be

present.

As we have previously noted, vitamins serve as activators as well as regulators. They can serve as activators of enzymes and, at the same time, as regulators of enzymatic activity; again, a very good example of synergism within the system and, also, a very good reason taking isolated enzyme factors may be disruptive of normal enzymatic activity causing fluctuations of precise temperature ranges necessary to conclude successfully an important metabolic process.

Enzymes act only within very limited temperature ranges, this being true also of catalysts used in certain laboratory situations and industrial processes. At about 94 degrees, food enzymes start to lose their effectiveness, their ability to fulfill their catalytic duties and at about 118 degrees, they are no longer of any use. At the other end of the scale, they start to become inactive at about 32 degrees and seem to be totally destroyed at minus 104 degrees Fahrenheit. Thus it is that baking, boiling, frying, stewing, roasting, heating of any kind, dehydrating and freezing will either reduce or completely destroy the enzymatic presence in food.

When it became known that some enzymes were contained in food and that they probably helped in the digestion thereof, many people began talking about "live" food, but this was a misnomer since enzymes are in no sense "alive," as we think of the meaning of this word. However, the concept of "life" in food led to many foolish ideas and fads in eating, some persons going so far as to eat nothing except what they were able to pull off a tree or pick from a vine or bush and pop immediately into their mouths, as if to catch the life element before it escaped. By this practice they hoped to live forever.

Certain supplement-happy practitioners go so far as to have blood tests made in order to evaluate the adequacy of pancreatic enzyme production, the same pancreatic enzyme which functions in the disorganization of carbohydrates in the small intestine. Since some of these enzymes are known to be absorbed from the GI tract into the blood stream, it is postulated that we can assess the amount of enzyme production by noting their presence in the blood.

Other methods are also used, such as the indican test which measures the amount of unused breakdown products which result in the absence of sufficient pancreatic enzyme to digest protein, these being directed to and collected in the urine. When such deficiencies are found to exist, supplements of pancreatic enzymes and perhaps even of hydrochloric acid are given to correct the situation instead of either reducing drastically the protein intake of the patient to one more in balance with normal enzyme production or fasting him to remove the toxic wastes that now burden his body preventing efficiency of production at the cellular level, a condition which probably exists throughout the body. In other words, an attempt to restore the enervated system to a condition capable of more efficient production on all levels, including the synthesis and utilization of enzymes, would be a more sensible way to approach the problem.

## **4.6 Research**

The enzyme ribonuclease was first discovered in 1938 by the bacteriologist Rene Dubos. (Ribonuclease acts as a catalyst in the hydrolysis of ribonucleic acid.) Eight years later Moses Kunitz, an American chemist, isolated this same enzyme and 23 years after that, in 1969, by two teams of researchers from Merck, Sharp and Dohme, the pharmaceutical company, and from Rockefeller University, this enzyme was finally synthesized. Since that time research has continued in many areas with the hope that enzymes can be manufactured and administered in the form of pills or by injection as agents in the prevention of disease or as a curative agent should disease exist.

Researchers are persistent. They have been hard at work learning about the chemistry of enzymes and how they work, trying to solve the mystery of how they can accomplish so much at such low temperatures. There is no doubt that much will be revealed in future years but, to date, we work on the fringes and have failed to solve the mystery.

## 4.7 Other Roles

Enzymes not only help to affect the marvelous processes of life but they also assist in death. Every minute millions of our body cells conclude their duties and die. Whenever cells die within the living body, they must be disposed of very quickly else the metabolic processes might soon be overwhelmed by the dead and dying cells and all life would necessarily come to a halt. This is where enzymes function in another capacity.

The dead cells are immediately set upon by the enzymes assigned to this specific type of cleanup duty. They are lysosomes. They disintegrate the clutter before it can obstruct normal function. Interestingly enough, there are no enzymes other than rigidly controlled lysosomes that can digest a living cell! Since enzymes lack this power, life is protected from destructive catalytic action and living cells just go on about their business.

Enzymes usually work at their point of synthesis within the cell where they are formulated. Their chief duty appears to be the building of proteins which are suitable for the particular host cell where they reside. Man is truly "fearsomely and wondrously made." And we labor under the delusion that supplementary enzymes can substitute for innate intelligence.

[Home](#) > [Lesson 39 - Food Supplements](#) > 5. Other Supplements

## 5. Other Supplements

Man has been very ingenious in attempting to find ways to make up for or compensate for his own shortcomings as to diet and lifestyle. We find persons who take yeast regularly. At first, they experience stomach pains which are early warning signs that the body is rejecting this vile substance but, as is usual, as the individual persists in ingesting it, the system soon accommodates to the poison, giving up vital force in doing so.

Anemic people religiously take their iron pills hoping to "cure" their anemia. While they may experience stimulation, they "cure" nothing. Their bodies continue to deteriorate both in structure and function. We know one woman who stoutly maintains that her anemic condition was "cured" by taking iron pills as prescribed by her physician. She has been taking these iron pills for over fifteen years. We look at her and wonder to what purpose as we see the pasty complexion, the curving spine and the appearance of premature wrinkles on her face. We ask, "But where is your health?"

Still others sprinkle bran on their morning cereal (cereals are not fit foods.) They add it to their salads and have cheer in the thought that they will be sure to have their morning BM. And yet, examination of raw bran under a microscope reveals jagged sharp edges which, in due time, will lacerate and tear away at the mucosal linings of the digestive canal and bring future sorrow and pain.

We know that substituting extraneously produced insulin for glandular insulin (produced by the Islets of Langerhans (located in, the pancreas) will, in time, about two years as a matter of fact, lead to the atrophy of that gland; and that using thyroxin as an aid or substitute for thyroid function will eventually deactivate the thyroid. We could recite a whole array of such supplementary "aids" to this, that or the other natural biological process, but one we wish to address at this time is the so-called "Starch Blocker."

The manager of one of our local supermarkets told us recently that he has never witnessed anything like it. People are buying this new fad supplement so fast that his store has difficulty in keeping up with the demand. Fat, people are lured into believing that they can lose weight rapidly while continuing to eat in a manner contrary to health.

The usual starch blocker is a legume derivative, high in protein. If the student will refer back to Lesson 23 in this course, he will understand why the starch blocker will do what it promises—namely, permit the person to eat extensively of carbohydrate foods and not gain weight, even to lose pounds. What the ads do not tell is that the Starch Blocker will prohibit enzymatic action on the sugar and starch goodies because the high protein presence provokes the normal acidic gastric response which, of course, more or less instantly stops carbohydrate digestion activated by ptyalin and other starch-digesting amylases.

This is anti-health self management of the worst kind, one that will lead inevitably to fermentation and putrefaction throughout the entire alimentary canal of all food eaten, not only of the carbohydrates; certainly an unhappy circumstances at best, one that, if continued, can be highly destructive of health. While the early prognosis may be favorable to immediate weight loss, the long-term prognosis for persons who continue to use a starch blocker instead of common sense, is bleak indeed. Life Scientists know that beauty, health fitness and a sickness-free extended life span can only follow in the wake of a lifetime of correct eating and living, not through the use of supplements or substitutes for reason.

[Home](#) > [Lesson 39 - Food Supplements](#) > Article #1: Disease, Stimulation and Therapeutics—A Question of Consistency

## **Article #1: Disease, Stimulation and Therapeutics—A Question of Consistency**

In the field of nonmedical care of the ill, a current topic concerns the use of "natural" treatments.

Treatments, therapies are artificial. "Natural therapy" is a contradiction.

The following is a Hygienist's view. There are some basic Hygienic principles which are frequently accepted in general discussion by proponents of Osteopathy, Naturopathy and Chiropractic. In practice these principles are often not merely neglected, but flouted. It is not the primary intention here, to present the proof-ramifications of these basics, but to make them clear, relate them to therapeutics and so show the incompatibility of therapeutic philosophies with Natural Hygiene.

Health and disease have a common ground—the living organism. Without life, there is no health; no disease. Disease is the expression of life in response to unfavorable circumstances. Health is the expression of life in response to favorable circumstances.

Toxemia is a poisoned condition of the organism. In toxemia, there is an accumulation of poisons, inhibiting efficient, normal function.

Enervation is a state of lowered nerve action, in which the nerve tissue's energy reserve is depleted; depleted through excessive nerve activity; activity necessitated by stimulation. Tired, exhausted nerves cannot adequately direct elimination. Reduced elimination increases toxemia. Toxemia stimulates. Toxemia compounds enervation and enervation compounds toxemia.

To break this vicious cycle and so overcome toxemia, the body suspends or reduces certain activities such as digestion and muscular effort. Thus the body conserves energy and nerve function which it redirects to make quantitative changes in its activities—to produce such actions as fever, diarrhea, polyuria, hyperhidrosis, vomiting—to remove irritating agents; that is, to eliminate. Such actions reflect the coordinated irritability of a complex organism. Irritability may be defined as that ability to take self preservative action in the face of adverse influences. Such actions are often labelled "disease."

Therapeutics is the art of altering the expression of the organism's irritability. We do not die from disease (our body's functioning) but from toxemia; from the causes of toxemia. To a large extent the body protects itself—but constant dripping wears away the stone. Any program of care that does not remove the causes of toxemia is not rewarded with health, for the body by virtue of its irritability will not cease

to be "sick," to be "diseased," to remove, or to accommodate to toxemia until success or death. If the need for disease is not removed, health will not ensue. This is another Hygienic principle. To seek, identify and remove the causes of toxemia is the constant aim of the Hygienist. The causes of toxemia and enervation are largely exogenous (i.e., from outside the body). The toxemia may be due to the accumulation of metabolic wastes or intermediary products of metabolism as a result of enervation, or to the absorption from the external environment of commonly recognized poisons such as drugs, preservatives, metals, poisonous gases, insecticides. In this article we are concerned with endogenous (internally) produced toxemia generated as a result of enervation; enervation due to exogenous influences—stimulants. The athlete who "runs" on a full stomach probably will not perform well—he certainly will not assimilate his food well; he will not do so because the resources of his body are directed to the performance of his athletic "feat." Digestion and alimentary assimilation are suspended because his body cannot perform all of its activities at a high rate, all at once. So when the body exerts itself in specific directions as it may do in response to the presence of drugs or other stimulants in order to remove them, normal routine elimination (the elimination of endogenous toxins) is reduced. Elimination is normally increased during rest and sleep, partly because of the relative reduction in stimulation at these times. So a stimulant, that is anything—physical, chemical, spiritual, mental—you name it—that necessitates body action which would otherwise be functionally, physiologically unnecessary and unrewarding to the organism results in toxemia and enervation. If we waste our vitality, our energies, our resources—in short, our life—then the level of toxemia remaining after rest and sleep is greater than it otherwise would be. So if there is a progressive waste of function and lack of rest and sleep, there is a progressive increase in the level of toxemia. This toxemia, the endogenous toxemia of stimulation is that which makes drugs (apart from their chemical toxicity) and therapeutic modalities whether "natural" or medical, objectionable to a Hygienist. The "Natural Theraputists" agents may be different to those of the medics but the effects are similar—stimulation, enervation, toxemia, disease...

*By Ian Fowler, A.A.I.M.L.T. reprinted from the June, 1973 Newsletter of the Australian Natural Hygiene Society in the June, 1977 issue of Dr. Shelton's Hygienic Review.*

[Home](#) > [Lesson 39 - Food Supplements](#) > Article #2: The Law of Stimulation

## **Article #2: The Law of Stimulation**

The body "sounds an alarm," in times of danger and immediately accelerates body action. Such is the effect whenever any toxic or irritating substance or influence is introduced into or upon the body. The system, under the controlled guidance of the brain and via the autonomic nervous network, then evaluates the situation and reacts with a suitable increased action, this action being impaired to an extent appropriate to the obstruction which is present. In other words, the amount of the impairment will be in direct proportion to the degree to which the action is accelerated.

All such increased action occasions an extra expenditure of the energy reserves ordinarily maintained by the body to cope with undue stress of any kind; for example, such increased action might be an extraordinarily high pulse rate. The result of this unusual expenditure, of course, is to lessen the availability of reserve power and, hence, of the ability of the individual adequately to meet challenges and stresses as they may arise at some future time.

We call anything which causes this increased action on the part of the body, a "stimulant." Of course, the immediate effect of the stimulant is that which is most, evident, that the stimulant is working and doing "good". This feeling of well-being is only temporary, however, since while the stimulant appears to do good, it is actually doing harm, the extent of the harm done being dependent upon, and in a precise ratio to, the amount of power called into play to produce the accelerated response, the feeling of well-being,

of euphoria.

This is the Law of Stimulation. It reveals the physiological consequences of false deception. It pertains to all stimulants: drugs (vitamins, etc.), coffee, tea, cocoa, alcohol, nicotine, even to snake venom which is currently being extolled as a "miracle" treatment in the care of victims of muscular dystrophy, the effect of many of these stimulants being extremely exciting; and also to lesser ones such as the various herbs, onions, garlic and the like. All *appear* to do good, but all perform a disservice to the body in that they do lasting harm, the harm being due to the fact that they reach into the body's energy reserves to accomplish the good they appear to do and *offer nothing in return which is of lasting value*. Their efforts are cumulative and remain with the person who employs them. The sense of euphoria occasioned by their use is *always* followed, in time, by a depression due to the expenditure of power required, as we have seen, to bring about the exhilaration in the first instance.

Certain stimulants are said to "act" on certain parts of the body as, for example, digitalis is said to "act" on the heart. The exact opposite is true. In this case, the heart is already weak and the digitalis only serves to weaken it further. All stimulants are useless to the body. They cannot become a part of the body; they cannot be turned into blood, flesh, or bone. They present an encumbrance to body action and, for this reason, a threat to efficiency and a hindrance to perfection.

The human body is designed for efficiency and for perfect performance. Accordingly, whenever it is threatened even in a miniscule way, it makes operational its defensive measures in an effort to eradicate from the system the threatening substance or influence. Thus, it will expend power *beyond the norm* to cleanse the body of the offensive substance and to prevent the resulting raid on the banked energy reserves.

Let us emphasize also that stimulants do far more than speed up the vital organs and related parts. They do far more than waste the vital reserves. In addition, and most importantly, stimulants such as tea, coffee, horseradish, alcohol, mustard and the like actually inflict an injury of some magnitude upon the very tissues with which they come in contact. In other words, their use wounds and hardens the cells and it is because of this wounding and the necessity thus imposed upon them by the danger to protect themselves from further injury, that the cells begin their defensive action, whatever it may be.

This defense may take place in degrees, the first amounting to little more than a mild exaltation, or increase, of cellular function. The milder the stimulant, the milder the irritation and the less the speeding up of cellular activity. This kind of stimulation, the kind that threatens cellular integrity, must always be differentiated from the stimulation and revitalization which are observed following proper nutrition which serves to renew body reserves. (Compensatory Stimulation.)

No tonic or drug will have an effect on a single tissue or on a single organ of the body, nor on just a few isolated tissues, organs or cells. The very physiology of the body, the fact that the blood flows freely to every unit of life within the total physical structure underscores the reality that such is impossible. The effects of any drug, of any tonic, of any other irritant are wholly systemic; that is, they are unlimited insofar as their area of involvement is concerned. The extent of systemic undermining, the damage done, is an individual affair, some persons being affected more, others less; but all being reduced to an extent in keeping with their individual strengths and weaknesses, simply because, for an immediate effect, they have sacrificed some unknown amount of the essentials of life: perhaps and surely, some irretrievable loss of energy plus an undeterminable amount of tissue damage which will remain as a handicap throughout life to efficiency of function, even though it be only in the form of weak scar tissue.

There is, of course, always the danger of pushing beyond the powers of life, as many a drug user has found out, too late. It is now simple for us to understand how and why this can occur when we realize that any stimulant which is uncompensated brings about the expenditure for the vital living power of the body, the force that sustains life. Stimulants do not and cannot supply this power. Once the power has been used, the person so depleted has lost it forever, and this is why the feeling of exhilaration induced by drugs is always followed by increased weakness. With the constant use of uncompensated stimulants, the force of life is gradually tapped and drained away. The lesson should be plain. The constant use of

coffee, drugs, vitamins, even herbs, will slowly, or rapidly, destroy the essence of life as they are used and according to the inherited constitution of the user.

Let us make a further point. The action by the body is *always* forthcoming, always there, the extent to which it is exhibited being wholly dependent upon the power which is available. In other words, loss of vital power will be experienced by *every* person; the stronger the person, the stronger the response; the weaker the individual, the weaker will be the response.

We, of course, cannot see this expenditure of the body's life immediately. We cannot watch an alcoholic, for example, and say, "Ah! Ha! There it goes!" Certainly not, but we do notice it as we are using it because in the using lies the stimulated euphoria. One moment the alcoholic's hand may be trembling but give him a drink and he will soon be "on top of the world," as we say, with all trembling gone. His euphoric state came from increased vital action which yielded up part of his "bank account."

We only become conscious of our lack of energy after the bank account has been raided too often—when our power supply is too low. We can observe a similar circumstance in our car battery. When it has power in reserve, we are pleased with its performance but the very use of that power depletes its reserves and the time comes when the source of energy fails us to the extent, perhaps, that the lights no longer glow and the car will not start. We are not able to see the energy stored within the battery, we could only observe it at work—when the lights glowed and the motor hummed. The same is true of the human body. In sleep, we display no sign of the power gathering in the slumbering body. The stimulant causes the power to be used and brings no power with it to replace that which is expended. Sound nutrition, on the other hand, always replaces the reserves which are expended in the performance of all of life's activities. Sleep restores the energy bank.

Herbert M. Shelton states the Law of Stimulation as follows: "Under all circumstances, vitality or energy of any character whatever is invariably manifested or noticed by us, as energy, in its expenditure, never in its accumulation." Herein, of course, lies the fallacy of modern medical practice as it pertains to the use of drugs to "cure." We seem stronger when we use drugs (commercial vitamins and minerals are drugs) only by the expenditure of our vital force, but we grow weaker as we steadily draw upon the reserve energy supply of the body. Unfortunately, in today's medical practice, the weaker the person is, the more it is thought that he must be propped up or goaded into a false sense of well-being by applying some drug or other means of "support" (as, for example, vitamins, mineral and other supplements).

The exact opposite, of course, should be the practice! The weaker the individual, the more he must be left alone to husband his resources, he must be left alone so that the pendulum of energy can swing once more in the opposite direction. Efforts to stimulate, sustain, and invigorate the tired, sick body by the use of any kind of tonic—the whipping effect—always produces an equal and opposite reaction—depression of both vigor and function. This is the Law of Stimulation and it is always in effect under all circumstances, in sickness and in health. False stimulation can produce no fruit of lasting value.

[Home](#) > [Lesson 39 - Food Supplements](#) > Article #3: Patients Dilemma: Who's Taking Care of Them? by Mrs. Elizabeth McCarter

### **Article #3: Patients Dilemma: Who's Taking Care of Them? by Mrs. Elizabeth McCarter**

Current articles and editorials on medical malpractice suits and the physicians dilemma are most

interesting, but one aspect of the situation has escaped attention—the patient's dilemma.

Not many doctors are aware that many of their patients, particularly the elderly, live in a state of quiet desperation and fear, afraid of the very persons on whom they must rely for healing.

Older people, for various socio-economic reasons, tend to live in communities with their peers, and they are acutely aware of what occurs daily among their neighbors.

Mrs. X has an eye infection. Her trusted doctor informs her she has a severe condition and that he will use a new drug. Two days later her pain is intense, her face swollen.

Now her doctor informs her she is allergic to this new drug and takes her off all medication. The condition heals itself.

However, damage has been done and she will never see quite so well again. Mrs. X has a dilemma, to be sure. She has impaired vision.

Mrs. Y has been seeing her doctor regularly for 25 years having a thorough examination every six months. She has been a good wife, mother, never smoke or drank or indulged in any degenerative practice. "Suddenly" she has a heart attack.

After several weeks she recovers sufficiently to return home from the hospital. Three weeks later, in self-examination, she discovers a lump in her breast, whereupon a massive mastectomy is performed. Discharged after what is termed "successful" surgery, she has another heart attack, more hospitalization, followed by two years of semi-invalidism with many angina attacks.

Perhaps rightfully, she wonders "why?" Why hasn't she, in all these years, received some counsel from her physician in preventive methods?

Mr. Z goes to the hospital, a victim of drug overdose. He was taking a prescribed heart medication in the prescribed dosage.

He almost joins the "up to 140,000" who die each year in hospitals as a result of *drug overdose* under the "care" of licensed nurses and physicians, a fact reported by a spokesman for the American Medical Association (AMA) last year before a Senate committee. The committee also heard testimony that *80 percent* of the deaths were preventable.

Even more shocking was the article in the Washington Post on May 24, 1974, which cited evidence indicating that 30 to 40 percent of all hospital patients suffer from adverse drug reactions.

In Los Angeles County a study showed that, of 50,000 prescriptions written, 13 percent were in amounts in excess of the maximum amount needed for ordinary therapy. The computer revealed that one patient had been given 54 prescription drugs in 112 days!

I have before me a copy of the Merck Index of drugs and it is a formidable volume containing more than 10,000 drug formulations to choose from.

The thought occurs to me that no one person could conceivably know all there is to know about these drugs. Furthermore, as a graduate chemist, I wonder how it would be possible even to predict what certain combinations of drugs would do within the the human body.

And yet, I know of a patient who received 26 different drugs in a single day! The potential in this chemical madhouse would confound the most learned biochemist, to say nothing of the human body thus impregnated!

The indiscriminate giving of drugs and combinations of drugs by anyone is tragic in the light of the accepted fact that the biochemical knowledge at our disposal today is rudimentary. The stupidity, thus, of giving numerous drugs in unproven combinations is enormous.

Is it any wonder so many elderly and less elderly patients succumb in a hospital? Such a situation poses an interesting problem for the legal mind. Are such deaths murder or manslaughter?

When and at what point does ignorance cease and responsibility begin? Should the physician be required by law to inform his patients that a particular drug has been known to cause death in other patients under similar circumstances? Should the physician be limited only to those drugs that have been shown in double-blind tests on a sufficient number of patients to be instrumental in cure and not in death?

When one adds to the drugged victims the startling reports published recently in the San Diego Union that as much as 20 percent of the surgery performed in this country is done by incompetent doctors, the tragedy mounts in its implications as does the fear among patients.

Dr. Jean Mayer of Harvard cites figures from the World Health Organization which show that the U.S. has dropped from 11th place—just 25 years ago—to 37th place in health care standards among the civilized nations in the world. Roger Rappaport in his article, "It's Enough To Make You Sick," states that our vaunted medical know-how has "failed to keep our male life expectancy rate equal with that of nations that have considerably lower per capita incomes."

Other evidence shows we have more heart trouble, more cancer, more diabetes and other so-called degenerative diseases than in any other country where statistics are available. Cancer is the number one killer of our children. As a nation we cannot afford this tragedy.

The facts suggest that the medical fraternity may have failed in its sacred trust. It may be that this period in time will become known as the Dark Age of Medicine.

### 1. Introduction

Since early Egyptian times, it has been recognized that obedience to physiological law is a prerequisite for maintaining health. Hippocrates is supposed to have said that the physician should have two special objectives regarding disease, namely, to do good or to do no harm. According to the Hippocratic concept, the doctor is the servant, the "helper" of pthisis (nature). He said, "It is important to help, or at least not to harm."

The very early physicians knew of the importance of obeying these natural laws and their practices evolved around this concept. Today there is an increasing body of scientific evidence which supports these concepts and more attention is now being devoted to diet, exercise and the other natural essentials of health.

During the very early years when man was evolving into the being we know today, he knew nothing about science and medicine yet his bones healed, his wounds healed and life went on. Primitives, like animals, instinctively relied upon their own intrinsic powers of healing.

During the 19th century, medical sects arose out of opposition to the so-called "heroic" treatment of their day and they shared some success. When we study each of these sects which arose during that time, we begin to see certain patterns emerging. The highest success rate was among those practitioners who did the least harm and allowed "nature's healing powers" to work unhampered.

By "nature's healing power" I do not mean a specific entity for healing but a capacity which resides in all living animals to heal themselves and to maintain a steady state. The goal of life is to maintain life and the body always strives toward a healthy state. Problems arise when too many obstacles are thrown in the path of this effort. The role of the Hygienic practitioner is to remove those obstacles by teaching his students how to correct those errors in living which caused his illness and making sure that all of the

conditions for health are supplied in the proper quantity and quality. It is important that all of these conditions are present at the same time as health cannot be achieved if any of them are missing or lacking. These conditions include proper food, pure air, pure water, sunshine, rest and sleep, exercise and emotional poise. The body then becomes the healing force. This is demonstrated in wound healing, healing of broken bones, in self-limited diseases such as colds, flu, etc.

When we consume such unnatural and unwholesome foods as the highly refined products which are so popular today, we build disease. We inflict our illnesses upon ourselves by poor dietary habits, lack of sleep, a sedentary lifestyle and other unhealthy habits. We then develop atherosclerosis, cancer, kidney stones, or ulcers from our own wrong actions. We cannot eliminate these errors in living by taking a drug. We must look amongst our practices for the "cure."

The cell is a homeostatic mechanism requiring precise entry of nutrients and elimination of wastes. These wastes result from ongoing metabolic activity and the deterioration of structural elements. With proper nutrition and detoxification, the cell is programmed for specific functions. Assuming these functions are healthy cells and tissue that lead to healthy organs that lead to a healthy organism.

Since illness is the result of unhealthful practices, then health should be restored by removing these causes and supplying the conditions for health. This is the philosophy of the drugless practitioners. They do not add further contaminants to an already toxic organism by dispensing drugs but rely on natural means which depend upon the body's own ability to heal.

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > 2. History Of Drugs

## 2. History Of Drugs

The oldest known written record of drug use is a clay tablet from the ancient Sumerian civilization of the Middle East. This tablet, made in the 2000's B.C., lists about a dozen drug prescriptions. An Egyptian scroll from about 1550 B.C. names more than 800 prescriptions containing about 700 drugs.

Ancient peoples used many drugs. An Egyptian physician, for example, tried to cure blindness by pouring a mixture of honey, pig's eye, and other ingredients into the patient's ear. But occasionally people who had taken drugs as remedies would recover naturally. As a result, they credited the drugs for their healing.

Throughout the Middle Ages, the demand for drugs remained high and pharmacies became increasingly common in Europe and the Arab world.

In the early 1500s, the Swiss physician Philippus Paracelsus pioneered the use of minerals as drugs. He introduced many compounds of lead, mercury, and other minerals in the treatment of various diseases.

The drug revolution began about 1800 and has continued up to the present. During this period, scientists have discovered hundreds of drugs. Scientists learned how to isolate drugs from plants in the early 1800s. In 1806, morphine became the first plant drug to be isolated. Within a few years scientists had isolated quinine and several other plant drugs.

The pace of the drug revolution quickened in the 1900s. In fact, most of the major drugs used today have been discovered since 1900, such as hormones, antibiotics, and sulfa drugs.

### 2.1 Herbal Medicines

Since early Neanderthal man, plants have been used as drugs for "healing" purposes. Even as modes of

medicine changed throughout the centuries, plants continued to be the mainstay of country medicine as methods and ideas on plant healing were passed down from family to family and within communities. Thus tribes, clans, villages, towns, sometimes entire countries, tended to have similar styles in "healing." Most of these plant remedies were based on local discoveries and pass-along uses, so many plants are used in exactly the same way.

For several thousands years the Chinese physicians used the Ma Huang plant. Later researchers extracted an alkaloid, ephedrine, from this plant.

Willow bark was used for thousands of years, even by American Indian tribes. Unfortunately, consistent use of the bark affected the digestive system, and it became imperative to find a substitute, or chemical version. This duplication took over fifty years of investigation, and was solved when a German scientist broke the chemical code by using the spirea plant family, instead of willow bark. He called his result aspirin, now one of the most used drugs on earth (resulting in much distress and iatrogenic diseases).

Curare arrow poison, another tropical discovery, is now used to control breathing during some surgery.

Digitalis was extracted from the foxglove plant, an herb, and is still prescribed by physicians for those with heart problems.

## 2.2 Shamen and Witch Doctors

In his book, *The History of Medicine*, the British physician and surgeon, Kenneth Walker says, "Thanks to the extraordinary recuperative powers of the human body and the resilience of the human mind, the patient generally managed throughout the ages to recover health in spite of the vicissitudes of treatment to which he had been subjected."

During the early days of civilization, there were many types of 'cures' that were associated with various cults. If the patient recovered his health, it was attributed to the healing ritual. If recovery did not occur, the disease was blamed. However, in all cases, it becomes evident that it was 'vis Medicatrix Naturae' which effected the recovery.

There was always a common denominator involved in all of these 'cures.' This is the force active in the organism in which healing takes place *in spite of* what was done and not *because of* what was done.

The Indians had their shamen and medicine men. The Hindus worshipped many gods and believed that illness was the work of demons. Therefore, rituals were performed to rid the sick individual of these demons and witches. The African bushman performed a symbolic dance which was supposed to "cure." The Chinese used acupuncture, herbs and moxibustion. (This is the burning of powered leaves of the moxa plant on the skin of the patient).

All of the therapies differed widely—from magic and witches to acupuncture. The modes of treatment were varied and often bizarre but they all had "success." Patients overcame their illnesses in most cases. How can a superstitious ceremony overcome a disease? The answer is that it cannot. First of all, most diseases are self-limited and the patient becomes well in spite of the treatment. But there was always this common denominator present in all of the recoveries and that is the vital faculty within each of us which is called upon when needed to re-establish equilibrium within our body and to heal. It is this vital power which we call 'nature' that healed the Indian after the witch doctor performed his magical ritual and it was this same force which manifested itself after the Chinese doctor administered herbs. The highest success rate came after those ceremonies or rituals or treatments which did the least harm and interfered least with the body's innate ability to heal itself.

### **3. What Are Drugs?**

Pharmacologists consider all chemicals that affect living things to be drugs. Stedman's Medical Dictionary defines a drug as "A therapeutic agent; any substance, other than food, used in the prevention, diagnosis, alleviation, treatment, or cure of disease in man and animal."

The truth is that all drugs are poisons and always do much harm, even when taken in small quantities. The body reacts defensively to all foreign substances which are introduced. This response is mistakenly attributed to the action of the drug when in fact the drugs do not act mechanically to produce any response. It is the body which acts upon the drugs in its efforts to dispose of this dangerous substance as quickly and efficiently as possible.

Hygienists know that the living organism is dynamic and full of energy. Its self-reparative and restorative ability remains intact as long as energy is abundant. Over 100 years ago Dr. R.T. Trall demonstrated the difference between lifeless matter and the living organism. He said that the living organism is active and the lifeless matter is passive.

Drugs are passive inert substances which have no magical powers to impart life and health to a living organism. Drugs combine chemically with the chemical constituents of the body where they do much harm by interfering with normal life processes.

### **4. What Do Drugs Do**

#### **4.1 Drugs Produce Disease**

People take so-called headache remedies, stimulants, anesthetics, pain killers, sleeping pills and narcotics for the temporary relief they afford. As a direct consequence of drug poisoning, gastric ulcer, anemia, kidney disease or any of many other ailments many develop. The pathologies these poisons occasion are added to the disease for which they are given. This is to say, physician-made diseases are worse than the natural disease.

It has been said that drug-treated patients have to recover twice—first, they have to recover from the original disease and, second, they have to recover from the drug-induced disease. The fact is that every drug is a poison and every drug produces disease. All too often patients are killed by the drug and, in an even greater number of cases, where the drug does not kill, it produces permanent harm. In fact, the most common cause of chronic disease is drug treatment for acute disease.

There are no harmless drugs; there are no safe drugs. All of them, even the least toxic, result in the production of pathologies, if they are repeatedly administered, even in small doses. It is certainly unwise to continue drug practices, especially in the face of the fact that they produce only ills. For example, what good comes from the administration of cortisone for arthritis? The symptoms are temporarily suppressed; the patient may be provided a certain measure of relief from pain, but the sufferer's condition inevitably becomes worse and recovery is more difficult. The ultimate result is increased suffering for a brief respite from pain. This is true of all suppressive measures. Both physician and

patient are deluded into believing that some suffering is being saved, but the later increased suffering outweighs the brief periods of freedom from pain. In fact, the increased suffering is usually of longer duration than the periods of comfort and is far more acute than the periods of "relief."

There are no drugs now used by the medical profession and there were no drugs used by any of the schools of medicine in the past that did not and do not produce disease.

## 4.2 Side Effects

If a drug, which is a chemical substance, unites with the protein of the cell, it destroys the cell. It is precisely to prevent this union and thus to save the life of the cell that the drug is resisted, rejected and expelled. All the action that is mistaken for drug action is cellular or organic action designed to protect and preserve life.

When a drug is picked up by the blood, either from the digestive tract or from the site of the injection, it is carried by this medium throughout the body, so that it comes in contact with tissues everywhere. The so-called side effects of drugs are the actions of the different tissues with which the drug comes in contact in rejecting, resisting and expelling the drug. So-called drug effects are not drug actions but vital actions.

If a drug may be employed and it suppresses symptoms, it is said to be good. That the drug may produce unwanted effects at the same time it suppresses the symptoms is, of course, unfortunate and the physician hopes that the "side" effects will not be too great or that he can stop the drug if the "side" effects threaten to become formidable.

Hygienists know how to avoid these poisonous effects. They simply avoid all drugs. We cannot be poisoned into health.

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > 5. Law Of Dual Effect

## 5. Law Of Dual Effect

The *Law of Dual Effect* states that all substances which are taken into the body, or which come in contact with it from without, occasion a twofold and contrary action—the secondary action being the opposite of the primary action, and the more lasting.

Therefore, the primary action (reaction) from taking a stimulant would be stimulating but the secondary and longer lasting effect would be depression. Likewise, the primary reaction from taking a pain-suppressant would be relief from pain but the secondary, longer-lasting effect would be increased pain. If the immediate and temporary effect of a dose of digitalis is to stimulate the heart, the secondary and permanent effect is to depress the heart.

Why would this be so? The body marshalls its available forces to handle the situation at hand which at that moment might be an abnormal substance in the form of a pain-suppressant. This toxin which has been so introduced has to be dealt with and eliminated as quickly as possible. During this time, the organism halts reparative and healing processes which are felt as symptoms, thus temporary relief.

However, as soon as the foreign substance is disposed of, the body reinitiates its healing processes with the return of the old symptoms. However, due to the tremendous expenditure of vital energy and the added toxins from the drugs, greater harm has been done. The heart becomes weaker after its stimulation due to exhaustion and added toxins. Likewise affected are all bodily organs.

## 6. What Drugs Cannot Do

Obviously, drugs cannot heal disease. There are no healing powers or intelligence outside of the human body. One should dismiss this notion of "cure" forever from their thoughts. It is only the body which possesses this potential to heal itself and will do so when favorable conditions are provided.

People take drugs for relief of their symptoms but often find that the drugs are ineffective even for this. People who take sleeping pills are more tired than ever. Dieters who take diet pills remain overweight.

The individual who has arthritis still has pain after ingesting enormous quantities of aspirin.

## 7. Why Drugs Are Used

Since 2000 B.C. man has sought that magical formula which would "cure" him of all his illnesses. Man sought an easy way out of his problems which he created for himself. "One pill and I will feel great once again!" Unfortunately, there are no magical formulas that will overcome our ills and still allow us to transgress all the laws of physiology.

Drugs are used to suppress symptoms. That is, to relieve pain, relieve insomnia, skin eruptions, constipation, etc. But are symptoms the disease? No, they are just evidences of it. They are a sign from our body telling us that the body has closed shop for cleansing and repairs. If one were to listen to the innate intelligence of his body instead of immediately suppressing these warning signs, many chronic diseases would not occur. Drugs suppress but never solve the problem of ill health (toxicosis). In fact, drugs cause more ill health (toxicosis).

It is commonly thought that every so-called disease is a distinct entity, requiring a specific remedy. Throughout all systems and methods of therapeutics, there runs a basic error that they call the therapeutic actions of their various procedures. The truth is that these so-called "therapeutic actions" or "remedies" are reactions of the body against the "remedies." The living organism reacts to everything within its environment—to assimilate useful agents and influences; to eject nonusable and destructive things. The defensive reactions against harmful substances and influences is proportionate to their harmfulness and commensurate with the vital energy possessed by the affected organism. These two factors—the amount and destructive-ness of the agent or influence, and the vital energy of the organism—are the determining factors in every reaction.

In reality the therapeutic effects are among drugs' evil effects. They are classed as therapeutic effects only because they are the effects the physician wishes to produce when he prescribes the drug. He assumes that something constructive and beneficial is accomplished when a symptom is temporarily suppressed.

When one uses drugs, one endeavors to provide the sick body with means of carrying on its healing efforts. By sending into it or applying to it, exotic and poisonous substances that it cannot use in a state of health, the body is actually further debilitated. In short, the effort to cure disease has been by producing additional disease.

Medical men employ poisons because they believe that poisons are the proper things with which to

restore health. They attempt to prevent disease by the employments of poisons because they believe that poisons can prevent disease. It never enters their minds that the elements of health are essentials to both preserving and restoring health.

Poisons are used because there is an effort to kill something—germs, parasites, viruses. This war is nominally on disease, but the warfare actually devolves upon the human constitution.

Should the sick be poisoned? One might also ask, should the well be poisoned? Is there any more reason the sick should be poisoned than there is that the well should be poisoned? If poisons are not the proper things with which to preserve health, why should they be thought of as the proper things with which to restore health? If poisons make the well man sick, what do they do for the sick man?

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > 8. Why Drugs Should Not Be Used

## **8. Why Drugs Should Not Be Used**

As you have learned from previous lessons, disease is a body-conducted remedial process. It is an effort on the part of the organism to repair and heal itself. You have also learned that disease is not something lurking in the bushes ready to attack the first person who passes by it. Rather it is occasioned by our own transgressions of life's laws.

Drugs cause disease and only disease. They do not prevent or eradicate it. Ingestion of drugs adds further toxins to an already toxic organism. Further, it is very enervating for the body to deal with drugs. The less vital energy the body has, the less equipped it will be to initiate healing.

Further, taking drugs does not solve the problem. One cannot attain health by suppressing symptoms. The problems of ill health still remain and the person is usually worse off than before he or she began taking the drugs. We are, in effect, telling our body a lie when we take drugs. We attempt to deceive it into thinking that this or that drug will be the "miracle cure." But in reality, we are hurting our body more by taking these poisonous substances.

Healing powers are possessed solely by the living organism. It is always in force and is forever functioning in the body in sickness or health. Hygienists cannot "cure"; they have no "cures." Neither has anyone else.

Outside of the human body, man cannot make blood; he cannot produce a cell; he cannot mend a broken bone; he cannot repair a wound. All that he may do is to remove all interfering factors, whether internal or external, and supply the normal conditions for life. After that, the organs and processes of life do the work of healing.

People do not become well if the causes of their illnesses are not discontinued and their modes of living are not corrected. Enervating habits cripple their functioning powers so that they remain toxic. They can get well as soon as they cease to build disease.

A toxic state of the body develops and slowly devitalizes the tissues for years, resulting in delayed healing and degeneration in injured or devitalized parts. When men live in a manner to maintain a continuous toxin saturation, they are in line for the development of any disease to which diathesis or environment determines them.

It is foolish to suppress symptoms. Let us consider a cough. It is a vigorous, forceful and dramatic expulsion of air from the lungs and is accomplished by sudden contractions of the walls of the chest and of the diaphragm. It is intended to force obstructing and irritating matter (mucus, blood, water, particles

of dust, smoke, gas, etc.) from the air passages. In pneumonia, coughing keeps the lungs cleared of exudate so that breathing remains possible. The cough is part of the remedial effort, not an attack upon the body from without. If the cough is checked or suppressed by drug devitalization, passages tend to fill with exudate. Checking the cough definitely, reduces the patient's chances of recovery.

Analogous to coughing is diarrhea. Like coughing, diarrhea is a dramatic acceleration of a normal physiological action. It is a bowel action and is, designed to free the colon, perhaps even the small intestines, of unwanted material. The unwanted substance may be unsuitable, or decaying food or drugs, or it may be a mineral water. In any case, the diarrhea is a remedial effort. To check the diarrhea while there is a need for it is to lock up, as it were, in the food tube the unsuitable material the diarrhea is intended to remove. The diarrhea automatically ends when its purpose is served and no suppression is necessary.

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > 9. What The Body Does When Drugs Are Taken

## **9. What The Body Does When Drugs Are Taken**

The first thing the body does when drugs are taken is to make an attempt at their removal through the bowels, the skin, the kidneys, the liver, the lungs, the mucous membranes, by vomiting or by other means.

Noxious materials within are either rejected or, failing that, shunted aside where they offer the least harm. Resistance and expulsion are self-preservative efforts on the part of the living organism. Sometimes due to lowered vitality, it is very difficult to expel certain toxic substances and may even be too difficult. Then the body adopts another technique for self-preservation—it stores them away in the bones' fatty tissues or even creates sacs called cysts or tumors for this purpose.

The poisonous quality of drugs that occasion vital defensive actions are termed the "medicinal action" of the drug.

Pharmacologists mistakenly believe that drugs have specific relations to various parts, organs, or structures of the organism, although they have never been able to verify it. Hence their belief in selective affinity, i.e. certain drugs act on one part of the body, and others act on other parts. Thus they classify drugs as cathartics, emetics, purgatives, diaphoretics, etc.

It is the body, the living organism, which chooses the way it can best expel drugs. Some drugs will be thrown out of the body via kidney excretion, which the pharmacologist will call diuretics, another by vomiting, and yet another by expectoration. Some drugs, because of their more poisonous nature, will be ejected by the body through as many channels as possible. Hence, its alleged "multiple actions."

Healing is a normal physiological or biological process. It results from the orderly operations of the ordinary and regular forces and processes of life, working with agents and substances that bear a normal relation to the living organism. Success of the body's efforts at self-healing depends absolutely upon removal of the cause of its ills. This is to say, the body mends itself when causes are removed. No healing can take place without removal of cause.

The force that is in any "medicinal action" is really vital power, that is, the power of the body itself. Understanding this property of living matter, we can clearly see that medicines do not at all act; do not furnish power for action; and do not in any mysterious way impart power to the body for its own action. The action occurring between the body and drugs is exclusively vital action, power being expended, not generated.

The organized body has remarkable powers of self-regulation, adjustment and distribution. When unhampered, it distributes its available energy to the various organs and tissues in proportion to their importance and needs.

Easily shown is that disease is a process of repair, renovation or healing; and that "cure" in the proper sense is nothing more nor less than the correction of those basic causes which necessitated, in the first place, the institution of disease. All disease phenomena exhibit vital action.

There is this relationship: unhygienic conditions of life give rise to a toxic state of the body. Toxicosis (or toxin saturation) develops beyond a point of vital toleration and evokes special eliminative efforts. These special efforts are the process called disease. Disease tends to free the body of its toxic overload. Disease is, itself, the healing process. Recognizing disease as the "cure," why employ drugs to stop it? Does that make sense? Is it working against the body's efforts to heal an exhibition of wisdom or ignorance?

Constructive disease is evidence of vitality. It is obvious, therefore, that therapy is anti-vital—destructive of the vital faculties of the body. Treatment by means of drugs is in reality directed against a beneficial, curative process. The remedy actually subdues vitality and with it physiological activity called "disease." This is harmful inasmuch as vitality is wasted, the restorative process is arrested, and poisonous substances are introduced into the system to lay the basis for further toxemic crises when vitality shall have been summoned to eject the "medicinal" accumulation. Thus the drug-treated body has a double liability: (1) The poisons introduced and (2) the continued retention of noxious materials because of suppressed remedial efforts.

To the extent that the body diverts energy to drug expulsion, to that extent a reduction in vital activities elsewhere in the body is occasioned. This usually results in the reduction of the remedial- process, or illness, not by removing its needs, but by a reduction of the vital power whereby it is conducted. Such a reduction comprises suppression.

It becomes apparent that you cannot indulge in the causes of disease and expect to be made free of its consequences. Physiology does not work that way. We cannot be made exempt from violations of Nature's laws.

The medical profession no longer advocates bloodletting, leeching, purging, puking, mercury treatments, tobacco and alcohol treatments, or a long list of other injurious and deadly practices of the past.

The medical profession, however, continues to defend drugging, vaccination, blood transfusion and a whole host of injurious and deadly practices. How long will it take them to admit the fact that these practices also require condemnation?

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > 10. Some Specifics

## **10. Some Specifics**

We know that all drugs are bad without exception. But to cite some specific examples, I will mention a few of the most commonly used drugs.

### **10.1 Acne Nostrums**

Acne most often appears on the face and causes much discomfort and embarrassment to sufferers because of its unsightly appearance. It is the result of accumulated toxins in the body which are being discharged

via the sebaceous glands of the skin. This condition results mainly from wrong diet and if this were to be corrected, the acne would disappear for the body would no longer need this outlet. However, many people attempt to suppress this cleansing effort by using acne preparations.

Acne products most often come in the forms of lotions or creams which are applied topically. The claim is that these lotions help heal and prevent acne pimples and absorb excess oil. As Hygienists, we know that nothing outside of the human body has the ability to heal and that, therefore, these claims are quite false. However, much harm can be done. One common ingredient in most acne preparations is benzoyl peroxide. This chemical is used on colored or dyed fabrics to bleach them white. When applied to the skin the body responds to the poison with reactions of itching, redness, burning, swelling or excessive dryness.

## 10.2 Allergy Relief Tablets

Allergy is also due to toxicosis. Allergy relief preparations are highly poisonous substances. The following warning is contained on Dristan Analgesic Tablets: "Warning: may cause drowsiness. May cause excitability especially in children. Do not take this product if you have asthma, glaucoma, difficulty in urination due to enlargement of prostate gland, high blood pressure, heart disease, diabetes, or thyroid disease."

Clearly, the body recognizes this as a poison and attempts to rid itself of it as quickly as possible. However, this requires a great deal of energy to deal with the poison and anyone who is so toxic as to display the symptoms of "allergy" would be particularly harmed to have an additional flood of highly poisonous toxins put into their systems.

## 10.3 Analgesics

Clearly, the most common analgesic taken today is aspirin. The first report of the therapeutic properties of the salicylates was by the Rev. Edward Stone in 1763. Today, world production of aspirin has been estimated to be around 100,000 tons per year with an average consumption of about 100 tablets per head per year. A large survey, as reported in the *Journal of Allergy in Clinical Immunology*, listed aspirin among ten drugs most frequently involved in adverse reactions. The first death attributed to aspirin ingestion per se, as distinguished from aspirin poisoning by overdose, was described in Germany in 1902. In 1933, Dr. B.R. Dysart published an article in the *Journal of The American Medical Association* describing death following ingestion of five grains of acetylsalicylic acid. Most aspirin tablets contain 400-500 mg. or about 7 grains. Recommended dosage is usually two tablets 4 times a day. This is quite a toxic load to deal with!

By 1970, Dr. R.S. Farr, in his presidential address before the American Academy of Allergy, was citing "the need to reevaluate acetylsalicylic acid" and suggested that, because of the risk to a substantial number of people, aspirin and aspirin-containing compounds should become prescription rather than over-the-counter drugs. Hygienists know that they are poisonous and should never be taken. They have no power to heal and cannot be used by our cells for any constructive purposes whatsoever.

In an article in the *Journal of Allergy in Clinical Immunology* in December 1976, J.R. Vane demonstrated that nonsteroid, anti-inflammatory drugs such as aspirin inhibit prostaglandin biosynthesis.

Interference with the biosynthesis of prostaglandins could have very grave effects on our health since this compound, which is present in all body tissues, plays a very important part in many physiologic activities. This includes, but is not limited to:

1. Facilitation of parturition by stimulating the contractions of the uterus.
2. Homeostatic regulation of blood pressure.
3. Regulation of exocrine as well as endocrine secretions.
4. Plays an important role in the negative feedback control of impulse transmission in the

sympathetic nervous system.

Also, prostaglandins inhibit secretion of pepsin as well as hydrochloric acid by the gastric mucosa by a direct action on the parietal cells of the gastric glands. (Parietal cells secrete hydrochloric acid.) This is one of the body's homeostatic devices.

Prostaglandins, then, are a control mechanism for secretion. As ulceration is believed to result from erosion of the mucosa by excessive quantities of gastric juice, the physiologic synthesis of prostaglandins by the stomach may protect the mucosa against ulceration by regulating its secretion.

If aspirin interferes with the biosynthesis of prostaglandins, then ulcers could more readily occur and this accounts for a common side effect of aspirin therapy.

So aspirin not only results in a great energy depletion within our body in its attempt to deal with it, its presence also interferes with many normal physiological functions. People create more harm than they realize when they ingest this commonly prescribed tablet.

## **10.4 Antacids**

An antacid is an agent given to neutralize acidity in the stomach. It interferes with the body's homeostatic attempts to maintain acid-alkaline balance, adds toxins to the body and never promotes health. The cause of acid indigestion must not be indulged. Here again, faulty diet must be corrected. If a person were to fast and then go on an all-raw food program of fruits, vegetables, nuts and seeds, all bodily functions would return to a healthy state.

Dr. Kiki Sidhwa says, "Milk and antacids, the mainstays of therapy for peptic ulcers, may lead to metabolic alterations potentially more serious than the primary disease being treated." He further says that such treatment might produce many changes in the system, including the development of gout. Explanation of the trouble was that this treatment upset the acid-alkaline balance in the system and led to alkalosis if long continued.

Antacids containing aluminum hydroxide inhibit the absorption of dietary phosphate since it binds this mineral in the lumen of the gut. Along with calcium, phosphorus contributes to mineralization of bones and teeth and is intimately involved in human metabolism. There is an important ratio between calcium and phosphorus which must be maintained. Great harm can result if any interference with this ratio occurs such as the binding of phosphorus when drugs are taken. A certain drug taken for a particular reason always has systemic effect.

## **10.5 Antibiotics**

Antibiotics mean anti-life and indeed they are against life. They are administered to kill life in the form of microorganisms. Since disease is incorrectly thought of as an attack by bacteria, germs, etc., the antibiotic is given to kill these "invaders." Instead they poison vital cells, that is, the body itself is killed to some degree. The body's efforts must then be redirected toward eliminating this new poison.

The cause of disease is not the germ that is present, but the mental and physical habits that have broken down the body. Let the office of the germs be what it may, they cannot cause disease. The theory that germs and parasites have to be destroyed in order to "cure" disease is a delusion.

Respiratory distress has been associated with ampicillin administration. Researchers have also demonstrated that several other widely employed drugs including isoniazid (an antibiotic) have produced clinical patterns of chronic (active hepatitis, resulting in cirrhosis). The scientists have found that drug reactions involving the liver result in liver toxicosis from the drug itself. In patients with drug-induced acute hepatitis, the incidence of bridging necrosis was increased. (Bridging necrosis is death of the threads of protoplasm which pass from one cell to another in the liver.)

The use of antibiotics has also been proven to result in many blood disorders including leukemia.

## 10.6 Antidiarrheals

Diarrhea is not in itself a disease but an action of the body against some form of toxic irritation, mainly from unsuitable or unhygienic foodstuffs. Dr. Sidhwa says that antidiarrhea drugs can result in kidney and liver disorders, skin and sight defects and even death.

Why should we poison ourselves and risk the chance of possible kidney or liver disease when all we have to do is simply provide the conditions for health and allow our body to repair itself? In this way we may be sure that we are not doing harm.

## 10.7 Cough and Cold Preparations

It is foolish to take any medication whatsoever when one manifests symptoms of a cold. From the Hygienic point of view, the cold is the "cure." The cold is the result of systemic poisoning and it is the body's effort to rid itself of some of its toxic overload. Any preparation taken to suppress these symptoms will only add to the toxins and will create another obstacle for our body to overcome while it is doing its "housecleaning" of toxic debris.

All drugs, including laxatives, sleep aids, stimulants, depressants, diet pills, etc., are aimed at treating symptoms. Hygienists do not treat symptoms but work at removing the cause of toxicosis which occasioned the disease in the first place.

As a student of Life Science you should always keep in mind that the body does not work in separate independent ways but it is a unified whole. The body performs all of its functions as a whole and even though a certain symptom of disease may manifest itself in a particular part of the body it does not mean that the whole system is not involved.

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > 11. What To Do Instead Of Taking Drugs

## 11. What To Do Instead Of Taking Drugs

The Hygienist does not accept "cures." What are we trying to "cure?" Attempts to "cure" actually suppress or stop the body's defensive and remedial processes. As the body is attempting to get well, we are trying to prevent it from getting well. This is the essence of cures.

What we're concerned about then, in health and disease, is removing the causes of disease, supplying the body with its basic needs so it may build health. Health is the organism's natural tendency toward the ideal and everything in the moral organism works toward health. We don't have to make the body healthy; we only have to live healthfully.

An obese person does not become healthy by taking diet pills. He must examine his diet and lifestyle and remove the causes of his obesity in order to attain health. We have to stop people from making themselves sick.

We must examine the person's way of life: what it is they're doing that they shouldn't be doing, the things they're not doing that they should be doing, and attempt to discover the causes of their trouble.

When we investigate these factors and remove the causes of disease, then we outline a program which will provide the conditions and circumstances necessary for health. The organism will restore itself to normal providing, of course, that it hasn't been irreversibly damaged.

It may be helpful to ask yourself the following questions:

**1. Am I eating the proper diet?**

By "proper diet" we mean one which we are biologically meant to eat. That is, fruits, vegetables, nuts and seeds—all eaten in their raw state. This is very important. Of equal importance is the amount that we are consuming. Not only the quality of our food is important but also the quantity. Ask yourself, am I overeating or eating when I am not really hungry? Eating food in the absence of hunger or consuming more food than our body can handle will lead to toxemia as sure as if we were subsisting on a diet of refined foods. So keep in mind quantity and quality when examining your lifestyle.

**2. Do I consume the purest water available?**

By this we mean only pure H<sub>2</sub>O and this is not available from your kitchen sink. Pure distilled water is the only kind that we should drink and then only when we are thirsty. Some people have the mistaken idea that drinking excessive amounts of water will "flush" the kidneys and "clean out" our systems. This is nonsense! Water is inert and has no such cleansing powers. However, when consumed to excess, there can result a great energy drain on the eliminative organs. So, here again, keep the quantity and quality idea in your mind. Distilled water is best in the amounts compatible with your needs.

**3. Is the air I breathe fresh and clean?**

This is a tough one. Living and working in our polluted cities makes it next to impossible to breathe really pure air. However, there are some things that we can do. If it is possible to move to the country, do so. If not, at least try to stay away from smoke filled working situations (or look into purchasing an electronic air purifier for your office). It helps to live where the house is set at least a little way back from the road and trees between the house and the road will help block and absorb some of the pollution from the cars and purify the air.

**4. Do I get sufficient rest and sleep?**

Sleep requirements vary from person to person but generally if you wake up without the aid of an alarm clock and feel rested and energetic, then you have obtained enough sleep. If not, you had better go to bed a little earlier or take a nap during the day.

**5. Do I get enough exercise?**

Daily exercise is a must to maintain health. Set aside a certain time every day for exercise. About 30 minutes to one hour a day should be sufficient.

**6. Am I exposed to the sunlight at least a few minutes each day?**

Sunlight is beneficial and the main source for Vitamin D, but be careful and don't overdo it as excessive sunbathing can be harmful. Remember the quantity and quality.

**7. Am I constantly under stress?**

It is not always possible to avoid stressful situations but it is possible to learn how to deal with stress. Stress and emotions are a physiological occurrence and can result in many types of disorders.

Now that you have run through your little questionnaire and have determined the cause of your disease, every effort must be made to remove those causes. When the conditions of health are provided in the proper quantity and quality, the body will immediately begin its remedial processes.

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > 12.  
What To Do When Acute Symptoms Manifest Themselves

## **12. What To Do When Acute Symptoms Manifest Themselves**

First of all, do not take drugs of any kind and this includes the herbal remedies. The best thing to do when symptoms of a cold or flu, pain, skin eruptions, hay fever, headache, stomach ache, or any disease

symptom arises is to rest.

The body needs rest. That is, physiological rest. By this we mean rest of the entire body, of the muscles, organs, glands and digestive organs. How can we provide the body with such a rest? Through a fast. By this we mean no food—only pure water and rest in bed. This will provide the ideal conditions for the body to redirect its energies to the reparative process. It may be advisable to fast at a Hygienic fasting institute where you will be supervised by a competent Hygienic practitioner. After the fast is broken, eat only those foods that we are physiologically suited to eat—raw fruits, vegetables, nuts and seeds in compatible combinations. In addition, follow all the other requirements of health and you will find freedom from disease.

For example, the Hygienic care of the pneumonia sufferer is the acme of simplicity. It is not designed to "cure" anything. It does not reduce fever, check coughing, suppress pain, or force further exudate into the lungs. Hygiene does not seek to suppress or palliate symptoms. The death rate is reduced to almost nil. Rest in bed in a well-vented room, warmth, all the water thirst demands, no food of any kind until all acute symptoms have subsided, constitute the essentials of proper care. Thus cared for, the person with pneumonia will recover more certainly, more speedily and more satisfactorily. Nobody will prove to be allergic to Hygienic care nor have bad reactions, as many have when penicillin is administered. By the employment of healthful measures.

You have done your body a favor. You have built health with proper rest, food, etc. You have not destroyed health with pills and potions. The aim of life is to maintain life. This is the goal of every cell in your body. When you take drugs you throw road blocks in the path of the cells in their efforts to live and support your existence. Don't sabotage your body. Instead, assist life by providing the conditions for health.

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > 13. Questions & Answers

### 13. Questions & Answers

**My doctor says that all cases of arthritis are incurable. He also says that I must take 10 tablets of aspirin every day to alleviate the inflammation and that I may have to eventually increase that dosage. Will this much aspirin be harmful?**

Your doctor is correct when he says that he cannot cure arthritis. Hygienists know that only the body has the ability to heal. However, there have been many cases of arthritis which have completely recovered following a fast and a Hygienic lifestyle. Aspirin is a poison and the body will treat it as such. A small amount of aspirin will result in a certain amount of damage to the human organism but such large amounts will do much greater damage. The wisest thing to do would be to consult with a Hygienic practitioner and arrange to go on a fast. After that, adhere strictly to the Hygienic lifestyle and health will be realized.

**I have been on the 'pill' for a number of years since I do not want to have any more children. Am I doing any harm through this practice?**

Your body cannot condone the pill. It contains substances which suppress the normal hormone secretions. To be effective, the product must be taken regularly throughout a woman's reproductive life, and the method is attended by a multitude of ill effects besides being entirely contrary to the principles of natural, healthful living. Evidence has built up that the use of the pill carries with it many dangers. There is a liability

for strokes or cerebral hemorrhage and other conditions involving blood clotting. Reports of eye troubles following their use were reported in the United States, Canada, Australia and Great Britain. Numerous other "side effects" have been established.

Yes, this is a very harmful practice and should be discontinued immediately. If you are interested in a natural birth control method which is safe, read the book "Creation of Life" by Terrie Guay.

**When my doctor prescribes a drug for me, I presume he knows what he is doing and wouldn't dispense drugs which were not scientifically tested before they were placed on the market. Am I correct in my assumptions?**

Because poison effects always follow drugging, physicians must be regarded as a class of voodooists. Dr. Sidhwa states a case where it was found that a woman was given a drug for arthritis which resulted in degeneration of cells in the retina of the eyes. This eventually resulted in loss of 80 percent of her vision. Reporting on this case, the Washington Post said that "drugs potent enough to injure and kill are often prescribed casually and even carelessly because of excessive reliance upon drug salesmen."

The so-called scientific training concerning the drug apparently came from the salesman's touting of the drug.

We should simply keep in mind that all drugs are poisons and there are no safe ones.

**It seems that every time I take my medication I get drowsy. Why would this occur?**

The nervous system of man is highly complex. It is very sensitive and delicate in its structure and function. This highly-specialized system reacts very quickly and shows immediate and marked changes if substances inimical to its well-being are taken. Drugs can and do influence the structure and functions of the whole nervous system. Drugs interfere with the nervous system, hence functions are depressed and drowsiness occurs.

**Since digitalis is derived from a plant, wouldn't it be alright to take?**

There are many poisons in the plant kingdom and digitalis is one of them. Furthermore, even though digitalis was originally derived from foxglove, it is now made synthetically. Although digitalis is one of the most commonly-used drugs for treating heart failure, it causes noticeable poisoning in an unbelievably high proportion of patients who take it. When a drug is given to a man suffering from a weak heart, it weakens the heart still more. The impaired heart must now pump more blood with each beat to help get the drug out of the system. But the heart, in doing so, will exhaust itself more quickly than if intelligently left alone and the patient allowed to rest. The heart needs rest, not stimulation. Exhaustion of all the vital organs is the common result of such stimulation.

This lesson has discussed the harmful practice of drug medication. All such agents are harmful even in small quantities. They are anti-vital and cause disease. They have no power or intelligence to effect healing.

All disease is the result of systemic poisoning and one cannot achieve health by ingesting poisons. The cause of disease must be removed before healing can be realized. When drugs suppress symptoms they also suppress the body's healing process. Only the body can heal and will do so when the proper conditions are provided. These conditions include proper food, fresh air, pure water, sunshine, rest and sleep, exercise and

emotional poise.

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > Article #1: The Poisoning Practice by Virginia Vetrano, B.S., D.C.

### **Article #1: The Poisoning Practice by Virginia Vetrano, B.S., D.C.**

Beginning about twenty-five hundred years ago and making but little headway in public patronage until the time of the renaissance, the drug system has now completely blanketed the earth. So great has grown popular reliance upon the drug practice and so thoroughly have the people been indoctrinated in the belief in drugs, that the practice has become a greater threat to mankind than the nuclear bomb. The drug system is filling the land with side effects of drugs, filling hospitals with iatrogenic diseases, the jails with drug addicts, the mental institutions with drug-induced psychoses and the graveyards with the premature dead.

In the great main the drug system is a system of spectacular palliation. Physicians are for the most part engaged in providing the sick with temporary and doubtful relief from their discomforts. Instead of seeking for and removing the causes of suffering, physicians seem to be content to provide questionable and evanescent respite from pain and discomfort.

A patient says to a physician, "I have a headache, what should I do?" The physician is likely to reply, "Here, take this aspirin."

As an outstanding example of this kind of practice and its results, let me briefly go over a case history that I recently received from a guest of the Health School.

A young girl, age 21, arrived at the Health School with the following story: at the age of thirteen she developed severe abdominal pains and was taken to the hospital and operated on for appendicitis. Later it was discovered that this was not her trouble as she still suffered with the same pains after the operation. Her parents reentered her in the hospital for an exploratory operation, during which the physician found lymphatic tumors in the abdominal cavity. Soon after this operation she developed epilepsy, and had to make frequent trips to the hospital for tests. She had all the diagnostic X rays known and many other diagnostic procedures for epilepsy. There were an array of diagnoses, first hypoglycemia, then hyperglycemia, then high blood pressure, then low blood pressure. One diagnosis contradicted another, and there was no end to the diagnoses, but they never could ascertain the reason for her epilepsy. Her brain waves appeared normal on the electroencephalogram .

Every known drug for epilepsy was given her, but she said that they only made her worse. Her physician insisted that she continue taking the drug despite the increased incidence of her convulsions. In desperation he finally decided to use new experimental drugs, but with the same results—no decrease in her epileptic fits. Is it any wonder that she developed kidney trouble, after this treatment? Soon she couldn't have normal micturition but required a catheter. For five weeks straight, she was forced to have the catheter in place. During this time, she complained that 'they injected drugs through the catheter into the bladder in an effort to reach an infection. It was during this period in the hospital that she began losing the ability to walk. After this her sight and hearing became impaired. It was then that her physician told her parents that she wouldn't live and sent her home to die.

She was indeed a victim of the *curing* practice. There is no wonder that at the hospital she lost her ability to walk, see and hear, as she said she had to take 200 pills a day, every day. Furthermore, she was force fed, and had seven shots a day. Despite her continual complaint of lack of appetite, they made her eat.

Her parents took their dying child home. Here she became more a master of herself. She was disgusted with having to take so many drugs that were apparently making her worse. She said no one but a blind person could fail to see that she was steadily growing worse under this treatment.

When she arrived home, she had to be carried to bed. Sensing that the drugs were making her worse, and with the permission of her father, she quit 90% of them. She was afraid to quit all of them at once. Disgusted with the encumbering and uncomfortable catheter, she took it out. She noticed immediate improvement in her health. Her eyesight improved, her impaired hearing became normal and almost overnight she found that she could walk again. Within five hours her bladder was functioning satisfactorily.

When it was time to make her regular trip to the epileptic clinic, she walked in unaided. Her M.D. marveled at her improvement and called in other practitioners to show off the miracle. The girl that couldn't walk, that was dying just a few weeks before, walked in unaided! Her drugs were indeed miracle workers! He immediately prescribed more of the same. He never learned that she had quit taking most of her drugs. It was after this that she presented herself to the Hygienist.

Can she regain the high level health she had at birth? How much recovery can she make after being subjected to such treatment? It is doubtful that she can regain the high level health of which her pristine organism was capable. Drugs and surgery have made of her a cripple. This girl has adamant determination, however, and I'm sure that she will recover as much health as is possible.

The Hygienist has little to work with when a patient comes to him machine gunned with X rays, vandalized by the surgeon's knife and enervated by the drugging practice. Can you imagine a family afraid to try natural and harmless methods after subjecting their daughter to all the most pernicious practices of our times? Her family was against her from the start and she had to plead, beg and cajole them into letting her stay long enough to take a lengthy fast. Because of her medical abuse, I was fearful of taking her as anything may happen on a fast after such treatment, and her parents would have been the first to point an accusing finger.

At the end of 18 days of fasting they told her she would have to come home soon. I immediately broke her fast in order that she would be able to travel. She began having mild convulsions soon after taking juices, and developed a slight fever and symptoms of acute distress. There was nothing to do but place her back on the fast and let nature continue the healing process. Somehow she persuaded her parents to let her stay longer. They were very apprehensive and couldn't believe that she could live through 18 days of fasting. When she continued on through 58 days of fasting, they were sure she could not even walk down to the phone and talk to them. During the second fast she passed kidney stones. During her second fast and subsequently she had no convulsions and has not reported any since leaving here.

How soon she will reach positive and top level health depends upon how well she carries out her Hygienic living. But as mentioned at the beginning of this article, she will have her limitations because of medical bungling.

It is unfortunate but most everyone coming to the Health School has his limitations in recovery because of his prior use of drugs, X rays and surgery. It is not only the elderly, whose health has been wrecked by drugs and surgery, but younger and younger person's, organisms are impaired because of their physicians' poisons and their surgeons' knives.

Daily we receive clippings in the mail from Canada and the United States describing the evils attributed to drugs, but the drugging continues. Neither patients nor physicians lose their faith in magic potions. It seems that very few people ever lose their faith in the physician with his armamentarium of poisons. Despite all the enlightenment of hazardous effects of drugs in the papers today, physicians and their patrons cling to the belief in their efficacy and harmlessness. The drugging continues.

The title of an article received recently, is "No Drugs During Pregnancy," then in small letters "unless absolutely necessary." These were the words of Dr. Benirschlese, research pathologist of animal pregnancies. To prevent pregnant mothers from refusing drugs a loop hole is always left for the

physician to deem the taking of a drug absolutely necessary. Intelligent mothers, fearing it may hurt their baby, may balk at taking their physicians' prescriptions and ruffle their physicians' pride. He can then assure them that he is giving the drug only because it is "absolutely necessary" in each instance.

Dr. Benirschchle said "even such simple drugs as sleeping pills have unknown effects on unborn children." He continues, "We don't really know what effect different drugs have on the human fetus but we do know they bring about changes in animals."

Are we not of the animal kingdom? Are we intangible angels? We are of the animal kingdom and we have the most complex and differentiated organism of any animal on earth. Because of this complexity, many more things can go wrong with human physiology than with the physiology of a lower animal. We can also enjoy greater functioning capacity than the lower animals because of our increased complexity of structure.

A simple machine has fewer things to go wrong than a more complex one. The slightest change in complex machine will immediately upset its workings, whereas a little flaw in a simple machine may not result in any modification of the machine until the damage becomes immense, then it is easily fixed.

Being the most complex living organism, man is more sensitive to inimical agents and influences than are the lower animals. It has been shown that man is more sensitive to radiation than the mouse, so also is he more sensitive to drug poisons.

A significant remark made by Benirschchle was exactly what Dr. Shelton has been saying for years, that a "nine-month gestation period in humans makes research difficult and *long-term effects of drug use should be studied until a child is twenty years old.*" Minute impairments of vital organs from drugging may not manifest until a child has reached maturity. The increase in microcephaly, liver damage, heart trouble, kidney trouble, diabetes, and cancer in younger and younger people makes us wonder just how many of these young people would not have suffered if their parents had not taken drugs while these children were in utero.

The vigor that was manifested in our pioneers and in the Amerinds is not seen today in our youth and middle aged. This is certainly due in part to our greater dependence upon the medical profession to care for the slightest bruise, cut or headache, and the prescriptions of drug poisons given for these mild afflictions.

Recently a jury awarded a child \$500,000 because her mother was given demerol, a drug used to lessen pain during labor, and the child failed to develop mentally. The child was chronologically seven but had the mind of a three-year old. The drug was not supposed to be given to mothers of premature babies. Despite the prematurity of her baby, this woman's physician gave her the drug.

Another clipping received by mail stated "digitalis drug poisons many patients." The article states , "digitalis, one of the most commonly-used drugs for treating heart failure, causes some form of poisoning in an unbelievably unusually high proportion of the patients who take it." John Ruedy of the McGill University said this is happening because of "improper" use of the drug.

I should like to point out that there is no such thing as the proper use of a drug poison. They are poison no matter how given. They never prolong life but always shorten it, and make more uncomfortable whatever life is left in the patient. Drugs greatly lessen the person's ability to get well Hygienically. They damage and lessen the vitality of every organ and organ system in the body.

When a drug is given to a man suffering with a weak heart, it weakens the heart still more. It is like whipping a tired horse to make him go. He expands more vital energy to get away from the whip, but he wears out quicker. The impaired heart must now pump more blood with each beat to help get the drug out of the system by increasing circulation. But the heart, in doing this, will wear out quicker than if left alone and patient rests. The heart needs rest not *stimulation*. Exhaustion of all the vital organs is the common result of such *stimulation*. Premature death is the result of *stimulating* people into such good "health."

With 5,000 new drugs being created each year, we should all remain healthy until the age of 140. We actually see more and more of the crippling disease, that people can't get well of (even by Hygienic means). All drugging impairs the organism's ability to function.

Instead of removing the causes of the impairment, people are drugged into insensibility in order that they may continue in their disease-producing ways until there are so many organic or morbid changes in the tissues that full recovery is impossible. The *Tribune* medical reporter states that this is creating one of the most pressing challenges in medical history; that of how to prevent the new drugs from causing other illnesses or side effects. This has led to the development of a new science, *pharmacokinetics*.

The very name of their "new" science indicates that they do not yet know the relation between lifeless and living matter—the former being passive and the latter active, always. Kinetics indicates movement and drugs do not move but are moved by the body to various parts of the body.

Pharmacologists freely admit that they don't know how their drugs act, or how the drugs achieve their therapeutic effect or that they act at all. They don't even bother to try to prove that drugs act.

If physicians, pharmacokineticists and pharmacologists could begin with a valid premise, their conclusions would be more likely to be correct. They would soon learn that all drugs are as inert in the living organism as in the pill bottle, and that all action attributed to the drug is *body action*. They would soon realize that these actions, occasioned by the drug, are the actions of the living organism expelling the drug because it is not useful, hence poisonous. As long as they attribute action to inanimate substances, they will continue to confuse themselves about the true nature of the drugging practice, and fail to see the destructiveness of their poisons.

Because of our self-preservative instincts, if a substance is introduced into the organic domain that it can't use, the cells in immediate contact with the drug, via our magnificent complex nervous system, alert the entire organism to the threat to its integrity. It is not one part of the body that resists a drug but many parts acting as a whole. It is the integral organism which acts to expel the drug before it damages any one part too greatly.

Digitalis may be given to a man with a feeble heart and there is an immediate pick-up in the pumping ability of the heart, not because the drug acts on the heart but because the heart has to pump blood faster to the emunctory organs in order to save the whole from succumbing to the drug. The digitalis didn't stay in the heart; it didn't even have to be near the heart, for it to know that something poisonous was in the system and that it had to step up its activities in order to do its share in the expulsion and rejection of the nonusable toxic substance.

Because the living organism has done all the acting, its energy is depleted in exact proportion to the amount of work it has had to do to eliminate the poison. His functioning power is permanently lowered, and much rest is needed to recover from the depletion. The already weak heart is more feeble than before the digitalis was taken.

Trall frequently clarified the explanation of the fact that it is the living system that acts and not the drug, by the following example: if you introduce a drug into a dead person, there will be no action whereas there should be more action if the drug acted, because there would be less resistance from a dead person's tissues than a live one. But the dead body cannot vomit it, it cannot develop diarrhea, nor do its kidneys function to expel it. The drug does nothing to a dead body, except chemically combine with the constituents of its tissues.

This is the difference between drugging a live person and a dead one. The live person resists the chemical union, and as long as it is alive it will continue to do so. For the chemical to combine with the constituents of the cell would mean death of the cell, and the formation of a third substance unlike the two which combined to form it. The living organism fights with herculean force to prevent the chemical union, and in doing so sometimes dies in the struggle. The cells had to die first before the chemical could combine with their constituents.

A debilitated old person cannot resist a drug as well as a healthy young person, for the same reason that a dead person can't act. The debilitated person has less energy to expend in eliminating the drug. Trail points out that if the drug acted, it should act with more force in a weak person because of less resistance from the weak organs, but we see the opposite.

I cannot repeat too often that anything that the living organism cannot make into living tissue or use in any of its metabolic processes is a poison. Drugs cannot fit this qualification, and hence are all poisons. Some are more virulent than others, depending upon their chemical compositions, but they all cripple the organism to a greater or lesser degree, depending upon how much ability a particular organism has to eliminate them.

Cells, tissues and organs are damaged in resisting and expelling drugs. This results in impaired function. Because much of the damage to the organism from drugs is permanent, complete recovery is impossible in those who have been drugged for years.

The damages of drugs are legion and we could fill many volumes with their evil effects, but I shall end this article by stating that if you desire to recover your health drugging is definitely not the answer. Drugs hinder the healing process and occasion diseases of their own.

The causes of disease must be removed. Then, the primordial requisites of life must be supplied in keeping with the living organism's ability to use them. Then and then only will the living organism be able to return to health. It will make as full recovery as is possible, depending upon how much previous damage has been done by the drugs. The fewer the drugs taken, the speedier and more complete the recovery.

[Home](#) > [Lesson 40 - The Dangers Of Drug Medication: Over-the-Counter And Prescription Drugs](#) > Article #2: Principles of The Hygienic System by R.T. Trall

## **Article #2: Principles of The Hygienic System by R.T. Trall**

The Hygienic System, or the treatment of disease by Hygienic agencies, is based on the following propositions:

1. All healing or remedial power is inherent in the living system. The "properties" of drug-medicines, as they are called, are simply *morbific effects*.
2. There is no curative "virtue" in medicines, nor in anything outside of the vital organism.
3. Nature has not provided remedies for disease. She has only provided consequences or penalties for taking or doing those things which occasion disease, the disease itself being an effort to remove those causes.
4. Health is found only in obedience to the laws of the vital organism. Disease is the result of disobedience.
5. Health is normal vital action, or action in relation to things usable. Disease is abnormal vital action, or *action in relation to things nonusable*.
6. There is no "law of cure" in the universe; the condition of cure is obedience to physiological law.
7. There is one universal rule applicable to the treatment of all disease by Hygienic remedies, and that is to balance functional action. If this is done, no disease, however violent, will prove fatal.
8. Remedial agents do not act on the living system, as is taught in medical books and schools, but are ACTED on by the vital powers.
9. Disease is not, as is commonly supposed, an enemy at war with the vital powers, but a remedial effort—a process of purification and reparation. It is not a THING to be destroyed, subdued, or suppressed, but an ACTION to be REGULATED and DIRECTED.

10. Diseases should not be "cured." So long as the causes exist, the disease should continue. But the causes of disease should be removed and the *patient* cured.
11. Truly remedial agents are materials and influences which have NORMAL relations to the vital organs, and not drugs, or poisons, whose relations are ABNORMAL and ANTI-VITAL.
12. Nature's *materia medica* consists of *Air, Light, Temperature, Exercise, Rest, Food, Drink, Bathing, Sleep, Clothing, Mental Influences*.
13. The true Healing Art consists in supplying the living system with whatever of the above it can USE under circumstances, and not in the administration, of poisons which it must RESIST and EXPEL.
14. Drug remedies are themselves CAUSES of disease. Every dose diminishes the vitality of the patient.
15. DRUGOPATHY endeavors to restore health by administering the poisons which produce disease.
16. The Hygienic System on the contrary, restores the sick to health by the means which preserve health in well persons.
17. Diseases are caused by obstructions, the obstructing materials being poisons or impurities of some kind.
18. The Hygienic System removes these obstructions, and leaves the body sound.
19. Drug medicines add to the causes of obstructions, and change acute into chronic diseases.
20. To attempt to cure diseases by adding to the causes of disease, is irrational and absurd.

### 1. History

American Indians smoked tobacco in pipes long before Christopher Columbus sailed to the New World in 1492. Columbus brought some tobacco seeds back to Europe, where farmers began to grow the plant for use as a medicine that supposedly helped people relax. In 1560, a French diplomat named Jean Nicot—from whom tobacco receives its botanical name, "Nicotiana"—introduced the use of tobacco in France.

Commercial production of tobacco began in North America in 1612, after an English colonist named John Rolfe brought some tobacco seeds from South Carolina to Virginia. The Virginia soil and climate were excellent for tobacco, and it became an important crop there and in other parts of the South.

Most of the tobacco grown in the American Colonies was exported to England until the Revolutionary War began in 1775. Manufacturers in the United States then began to produce smoking tobacco, chewing tobacco, and snuff for domestic use. Cigars were first manufactured in the United States in the early 1800s.

Spaniards and some other Europeans began to smoke hand-rolled cigarettes in the 1600s, but few people in the United States used them until the 1850s. Cigarette smoking became increasingly popular after the first practical cigarette-making machine was invented in the early 1880s.

Hand-rolled cigarettes achieved limited popularity in the United States between 1855 and 1885. They contained either straight Turkish tobacco, straight flue-cured tobacco, or a blend of the two. The first practical cigarette-making machine was invented in the early 1880s. Cigarette companies introduced domestic blends about 30 years later.

## 2. The Tobacco Plant

Tobacco is a plant whose leaves are used chiefly in making cigarettes and cigars. Other tobacco products include smoking tobacco for pipes, chewing tobacco, and snuff.

Tobacco ranks as a major crop in more than 60 countries. During the late 1970s, the annual worldwide production of tobacco totaled about six-million tons. Farmers in the United States produce about 705 million cigarettes and about 3 1/2 million cigars yearly. About 160 million pounds of tobacco are manufactured annually for smoking tobacco, chewing tobacco, and snuff. The annual value of tobacco products amounts to about \$19 billion. Most of this income comes from domestic sales of the products. As you can see, many people are getting rich at the expense of the nation's health.

The government encourages and supports the growth and manufacture of tobacco and its products since it receives a large income through taxes on tobacco. Tobacco products are also taxed by all the state governments and some local governments. Taxes on tobacco total about three times the amount that the growers receive for their crops. The officials of our government are well aware of the health dangers of tobacco, yet they continue to support this industry.

Once tobacco is harvested, it goes through a curing process. This process produces various chemical changes in the tobacco that supposedly improve its flavor and aroma. There are three methods of curing tobacco: (1) air curing, (2) fire curing, and (3) flue curing. Each type of tobacco responds differently to each of these methods.

Air curing uses natural weather conditions to dry tobacco. Air-curing barns have ventilators that can be opened and closed to control the temperatures and humidity. This process takes from four to eight weeks.

Fire curing dries tobacco with low-burning fires. The smoke gives fire-cured tobacco its distinctive taste and aroma. Farmers regulate the heat, humidity, and ventilation in the curing barns so the leaves will not be scalded. Fire curing takes from three days to six weeks. This smoking process adds more toxins to the already toxic tobacco. It has been proven that anything that has been smoked is carcinogenic when ingested (as in cigarette smoking when smoke enters the lungs).

Flue curing dries tobacco by heat from flues (pipes) connected to furnaces. The temperature is gradually raised from 90°F. to 160°F. until the leaves are completely dry. The flue-curing method takes about a week.

Freshly-cured tobacco has a sharp aroma and bitter taste as would any poison. Therefore, most tobacco is put into storage and allowed to age before being used in manufacturing tobacco products.

Prior to storage, most tobacco goes through a redrying process, during which it is completely dried and cooled. Manufacturers then restore some water throughout the leaves to ensure uniform moisture content. This practice prevents the leaves from breaking.

Next, tobacco is stored for two or three years in barrel-like containers. During storage, it ages and undergoes a chemical change called fermentation (fermentation is decomposition of sugar and starch and their conversion by microorganisms to carbon dioxide, alcohol and acetic acid—poisonous by-products). This fermentation is said to give tobacco a sweeter, milder flavor and aroma and reduce its nicotine content. They are, in effect, exchanging poison for poison. Tobacco also loses moisture and becomes darker during aging.

A somewhat different procedure is used to age cigar leaf tobacco, which does not require redrying. Bales of this tobacco are placed in heated rooms or are simply hung up to ferment before storage.

If you were to take any healthful food (which tobacco is not) like romaine lettuce, and submit it to the same processing as tobacco goes through, you would end up with a toxic poison. With tobacco, you

begin with a poisonous plant and render it more poisonous through this manufacturing process.

Most tobacco grows best in a warm climate and in carefully drained and fertilized soil. Growers and consumers would greatly benefit by utilizing these ideal growing conditions for fruit and nut trees. Pecan trees, for example, produce abundantly, require little maintenance, and their produce is easily harvested. Pecans are in high demand for their superior flavor and nutrient value. They also bring a good price on the market. Tobacco is also heavily sprayed with expensive insecticides but this is not necessary (or desirable) with pecan trees. Tobacco has no nutritional or other benefits and its only effects are bad ones. On the other hand, pecans are high in protein of the best biological order and contain oils that are easily digested and utilized, thus making them useful dietary items. In addition, there are no harmful toxins.

[Home](#) > [Lesson 41 - Thanks For Not Smoking](#) > 3. The Dangers Are Realized

### **3. The Dangers Are Realized**

The use of tobacco products has been controversial for many years. During the 1500s, European physicians declared that tobacco should be used only for medicinal purposes. The Puritans in America considered it a dangerous narcotic. During the 1960s, scientists established that smoking tobacco products—especially cigarettes—could result in lung cancer, heart disease, and other illnesses.

Some cigarette manufacturers reacted to the medical findings by reducing the tar and nicotine content of cigarettes. However, doctors state that these measures have not eliminated the dangers of smoking.

Various federal laws have been passed in the United States regarding the sale of tobacco products. Since 1966, manufacturers have been required to include a health warning on all packages and cartons of cigarettes. Another law, which went into effect in 1971, banned radio and television commercials advertising cigarettes. In 1972, manufacturers agreed to include a health warning in all cigarette advertising. Some states have laws that prohibit smoking in various public places. Yet the sale of cigarettes continues to increase.

In 1978, about 38 percent of the adult men and 30 percent of the adult women in the United States smoked cigarettes. Cigarette smoking had been increasing rapidly in the United States until 1964, when 52 percent of the men and 32 percent of the women 21 years old and older smoked. That year, the United States surgeon general first officially warned of the health hazards of smoking. In 1979, the surgeon general issued another report strongly linking cigarette smoking to heart disease, lung cancer, and other ailments. In spite of knowledge about the dangers, many young people became smokers. In the late 1970s, about 19 percent of the boys and 26 percent of the girls in the 17- to 18-year-old group smoked regularly.

Three quarters of adults who smoke took up the habit before age 21. One hundred thousand children under the age of 13 are smokers. A government survey for 1979 showed there are 1.7 million teenage girls and 1.6 million boys who are regular smokers. Many more women are smoking today than they did 20 years ago. Correspondingly, the lung cancer rate for women has increased 500 percent during the past 20 years. Women who smoke more than a pack and a half a day run a significantly higher risk of a heart attack than women who do not smoke. And women who smoke and use oral contraceptives containing estrogen have ten times the chance of having a heart attack and of damaging blood vessels, compared with women who do not smoke and do not use oral contraceptives.

## 4. Tobacco Toxins

Cigarette smoke contains more than 3,000 chemical substances, and several of them have been linked to the development of diseases. The most dangerous substances are (1) carbon monoxide, (2) nicotine, (3) tars, and (4) smoke particles.

### 4.1 Carbon Monoxide

Carbon monoxide is a poisonous gas that interferes with the blood's ability to carry oxygen. It also contributes to heart disease and lung disorders and results in changes in the blood vessels that may lead to hardening of the arteries.

Symptoms of carbon monoxide poisoning include headache, vertigo, dyspnea, confusion, dilated pupils, convulsions and coma.

Carbon monoxide has long been recognized as a dangerous gas. It is present in concentrations of 1 to 5 percent of the gaseous phase of cigarette smoke. The amount of carbon monoxide produced increases as the cigarette burns down. Carboxyhemoglobin (union of carbon monoxide with the hemoglobin of the blood) levels in smokers vary from 2 to 15 percent depending on the amount smoked, degree of inhalation, and the time elapsed since smoking the last cigarette.

Carbon monoxide, which has 230 times the affinity of oxygen for hemoglobin, impairs oxygen transportation in at least two ways. First, it competes with oxygen for hemoglobin binding sites. Second, it increases the affinity of the remaining hemoglobin for oxygen, therefore requiring a larger amount of potential oxygen between the blood and tissues to deliver a given amount of oxygen. This situation usually results in a lower amount of oxygen in the tissues. It should be understood that oxygen is essential for most cellular activities and even a slight decrease can impair all bodily functions.

Carbon monoxide also binds to other iron-containing pigments, most notably myoglobin (a protein molecule found in muscle tissue), for which it has even a greater affinity than for hemoglobin under conditions of low oxygen. Researchers have not yet determined the exact significance of this binding but they do know that it is important in tissues such as the heart muscle, that has both high oxygen requirements and requires large amounts of myoglobin.

Carbon monoxide, at levels of exposure commonly reached by cigarette smokers, has been shown to decrease cardiac contractibility in persons with coronary heart disease. It has also been shown to produce changes like those of early atherosclerosis in the aortas of rabbits.

### 4.2 Nicotine

Nicotine results in stimulation of the nervous system and the heart and other internal organs. The effect on the nervous system is one of the reasons why people have such a hard time giving up smoking. Nicotine is poisonous. When any poison enters an organism, the body is stimulated to eliminate that poison. This condition soon leads to exhaustion and depression of all bodily organs. Nicotine may be a factor behind the many heart attacks and other conditions, including stomach and intestinal ulcers, that are related to smoking.

Nicotine is a colorless, oily, transparent vegetable chemical compound of the type called an alkaloid. It has a hot and bitter taste. It is found in small quantities in the leaves, roots, and seeds of the tobacco plant. It can also be made synthetically.

The quantity of nicotine in most tobacco ranges from 2 to 7 percent. It is most abundant in cheaper and

domestic varieties. Nicotine, as mentioned, is exceedingly poisonous. In a pure state, even a small quantity will result in vomiting, great weakness, rapid but weak pulse, and possibly collapse or even death.

Nicotine indirectly affects circulation by provoking catecholamine release. Catecholamide refers to active hormones, epinephrine and norepinephrine which are derived from the amino acid tryosine.

They have a marked effect on the nervous system, cardiovascular system, metabolic rate, temperature, and smooth muscle. The ingestion of nicotine induces a bodily response to rid itself of this poison. Thus, the body is stimulated and more catecholamines are released than would normally be the case. Heart rate increases and blood flow through the heart is also increased. The blood vessels going to the heart are constricted (due to the catecholamines) and this increases blood pressure. The presence of nicotine in the blood also results in an increase of serum fatty acids and creates the tendency for blood platelets to stick together. Nicotine also inhibits pancreatic bicarbonate secretions, resulting in a more acid condition in the body. This situation produces adverse systemic consequences.

### **4.3 Tars**

Tars contain small quantities of carcinogenic substances. They are believed to be one of the major factors that lead to lung cancer and other types of cancer among smokers.

The tar from cigarette smoke has been found to result in malignant changes in the skin and respiratory tract of experimental animals, and a number of specific chemical compounds contained in cigarette smoke were established as potent carcinogens or co-carcinogens. Malignant changes including carcinoma are found in the larynx.

### **4.4 Smoke Particles**

Smoke particles are as small as 1/70,000 inch. A smoker exhales most of the particles, but as many as 25 percent of them may be trapped on the lining of the lungs. The particles are later absorbed by cells in the lining. This absorption may cause the cells to function improperly and damage the lining of the lung. The particles can also cause excessive scar tissue within the walls of the lungs. Smoke particles probably help cause progressive destruction of the walls of the air sacs in the lungs of long-term smokers.

These, irritants cause immediate coughing and broncho-constriction after smoke inhalation; inhibit ciliary action of the bronchial epithelium; stimulate bronchial mucous secretion; suppress protease inhibition; and impair alveolar macrophage function.

[Home](#) > [Lesson 41 - Thanks For Not Smoking](#) > 5. Cigarette Smoking And Chronic Disease

## **5. Cigarette Smoking And Chronic Disease**

### **5.1 Lung Cancer**

Studies have shown that men who smoke more than one pack per day are about 20 times more at risk Of developing lung cancer than are nonsmokers. Laboratory experiments show that tobacco smoke condensate can produce skin cancer in animals and that animals inhaling cigarette smoke may develop cancer of the larynx or lung.

Based on evaluations of detailed clinical and experimental data accumulated over the last 30 years, cigarette smoking has been clearly identified as a causative factor in lung cancer. The risk of developing

lung cancer increases directly with increasing cigarette smoke exposure as measured by the number of cigarettes smoked per day, total lifetime number of cigarettes smoked, number of years of smoking, age at initiation of smoking, and depth of inhalation. Lung cancer death rates for women are lower than for men but have increased dramatically over the last 15 years, coinciding with the increasing number of women smokers. This increase has occurred in spite of the fact that women smokers use fewer cigarettes per day, more frequently choose cigarettes with filter tips and low tar and nicotine delivery, and tend to inhale less than men.

A person who stops smoking has a decreased risk of developing lung cancer compared to the continuing smoker, but the risk remains greater than the nonsmokers for as long as 10 to 15 years after the person stops smoking. The toxic residues from the cigarette smoke remain in the lungs for a long time but the body will eliminate them as quickly as possible. This depends upon the amount of vital energy that a person has. Elimination can be speeded up if the individual adopts a generally more healthful lifestyle in regard to diet, exercise, sleep and rest, etc. Also of great benefit would be a long fast. This speeds up elimination of toxins most of all, because energy is conserved during this physiological rest and redirected from digestion to healing.

Pipe and cigar smokers experience mortality rates from cancer of the oral cavity, larynx, pharynx, and esophagus approximately equal to those of cigarette smokers. The risk of developing cancer of the lung is lower than the risk of cigarette smokers, but it is significantly above that of nonsmokers. This is probably due to the fact that pipe, cigar, and cigarette smokers experience similar smoke exposure of the upper respiratory tract, while cigarette smokers (due to their greater tendency to inhale) have a greater exposure of their lungs to smoke than pipe or cigar smokers.

## **5.2 Chronic Bronchitis and Emphysema**

Chronic bronchitis and emphysema deaths are also about 20 times more frequent in people who smoke heavily. Both diseases can be produced in animals exposed to cigarette smoke. Pulmonary function tests often show airflow obstruction in the small airways even before chronic expectoration develops.

Toxins accumulate up to a saturation or "tolerance" point and then the body initiates a "housecleaning." At this point expectoration is seen. This is a sign of bodily healing and should not be suppressed. If you discontinue smoking at this point, the body will heal.

The adverse effect of smoking on mucociliary (hairlike processes on the mucous membrane that function to move excess mucus out of the lungs) clearance and on the normal balance between lung proteases (protein-splitting enzymes) and their inhibitors predisposes smokers to bronchopulmonary disorders and emphysema. As you can see, toxins from cigarette smoke interfere with many physiological activities. This situation always leads to acute, and finally chronic, illnesses.

## **5.3 Cardiovascular Diseases**

Cigarette smoking accelerates atherosclerosis and may double the risk of myocardial infarction. Smoking may precipitate a heart attack. The risk of developing cerebrovascular disease, peripheral vascular disease, or aortic blood clots is also increased in smokers.

Coronary heart disease is the most frequent cause of death in the United States and is the most important single cause of excess mortality among cigarette smokers.

Cigarette smoking and hypertension and elevated serum cholesterol are the major risk factors for myocardial infarction and death from coronary heart disease. The cause behind hypertension and elevated serum cholesterol would include accumulated toxins due to wrong diet and enervating habits along with cigarette smoking. Cigarette smoking acts both independently as a risk factor and synergistically with the other coronary heart disease factors. The magnitude of the risk increases directly with the amount smoked.

The formation of carbon monoxide from cigarette smoke with hemoglobin in the blood to carboxyhemoglobin; release of catecholamines—epinephrine and norepinephrine; creation of an imbalance between myocardial oxygen supply and demand; and increased platelet adhesiveness leading to blood clot formation have all been demonstrated in smokers and are proposed as explanations for the excess coronary heart disease mortality and morbidity among smokers.

### 5.4 Peptic Ulceration

Peptic ulceration occurs more frequently and has a higher mortality rate in cigarette smokers than in non-smokers. In addition, the rate of ulcer healing is slowed.

When an organism is enervated due to bombardment of toxins from cigarette smoke, it is less capable of healing. Vital energy is so depleted that normal functions slow or are halted completely. Adverse effects will be seen throughout the entire body as all poisons induce systemic responses.

### 5.5 Premature Deaths From Conditions Caused By Smoking

Number of Deaths	Immediate Cause of Death
80,000	Lung Cancer
22,000	Other cancers (oral, larynx, esophagus, urinary, bladder, kidney, pancreas)
225,000	Cardiovascular disease
19,000	Chronic pulmonary disease

[Home](#) > [Lesson 41 - Thanks For Not Smoking](#) > 6. Added Industrial Pollutants

### 6. Added Industrial Pollutants

It has been estimated that every year 15.5 million people risk exposure to pollutants at the workplace and 400,000 people develop illnesses induced by the job. Tobacco smoke may transform workplace chemicals into much more harmful agents.

There are 15,000 toxic chemicals in U.S. industry today; each year about 400 new substances are introduced. But safety levels have been established for only a small fraction of the chemicals. The results of the interactions among these substances are incalculable. Some of the many toxic agents identified that can contaminate tobacco products are lead, inorganic mercury, inorganic fluorides, boron trifluorides, formaldehyde and cabaryl.

Some toxic agents in tobacco smoke may also occur in the workplace, thus increasing the smoker's exposure to that substance. For example, over 20,000 workers in 75 different occupational groups have potential occupational exposure to cyanide, which can form a complex that results in the disruption of the function of the thyroid. Hydrogen cyanide is one of the toxic compounds in tobacco smoke. In a

study of workers in electroplating exposed to cyanide, the majority complained of fatigue, headache, tremors of the hands and feet, pain, and nausea.

Studies with other toxic agents, such as carbon monoxide, have shown similar results. Among blast furnace workers, it has been found that the levels of carbon monoxide in the blood of smokers is double that found in smokers not similarly exposed. Levels of carbon monoxide were 7.5 percent; levels in excess of 5 percent can result in cardiovascular alterations.

Among other chemical agents found in tobacco smoke as well as the workplace are acetone, acrolein, aldehydes, arsenic, cadmium, ketones, lead, polycyclic compounds. Workers in such places who smoke are twice exposed to toxic substances: textiles, coal mining, uranium and gold mining, paint spraying, welding, firefighting, cooking kitchens and rubber. Workers exposed to radioactive gas, chlorine and coke ovens face similar dangers.

[Home](#) > [Lesson 41 - Thanks For Not Smoking](#) > 7. Tobacco Subsidies

## **7. Tobacco Subsidies**

At the same time HEW had increased its budget to \$29.8 million for 1979 efforts to combat smoking, the Department of Agriculture ran a loan program to guarantee the tobacco farmer a fixed and high-support price. If the farmer's tobacco crop cannot be sold on the market at the fixed price, a federally-supervised stabilization corporation buys the tobacco with funds borrowed from the government. The low-interest rate for the loan is, to an extent, subsidized by the taxpayer.

The corporation holds the tobacco crop and can sell it later when the price is better. In fiscal 1979, the government loaned \$227 million for such programs and spent another \$9 million on tobacco research, grading, marketing news, and administration. More than half the loan monies were paid back within a few months.

In 1975 and again in 1979, the Surgeon General issued an official government document warning the U.S. citizens about the dangers of smoking. In these books (published by the U.S. Department of Health, Education and Welfare), extensive scientific evidence supports the fact that cigarette smoking is a life-threatening habit. Yet, the government continues to support this poison habit.

[Home](#) > [Lesson 41 - Thanks For Not Smoking](#) > 8. Effects On Fetus And Children

## **8. Effects On Fetus And Children**

If a pregnant woman smokes, it has adverse effects upon her unborn baby. There is abundant evidence that maternal smoking directly retards the rate of fetal growth and increases the risk of spontaneous abortion, of fetal death, and of infant death in otherwise normal babies. There is also some evidence that children of some smokers are more likely to have measurable deficiencies in physical growth and development.

When the mother smokes, some of the harmful gases and poisonous substances in the smoke actually pass from her blood through the placenta and into the fetal bloodstream. One of these gases is carbon monoxide, which forces oxygen out of the red blood cells. Another powerful poison, nicotine, adds to

the damage by narrowing blood vessels, including those in the placenta itself. This decreases the amount of oxygen and food delivered to the unborn baby.

Although the fetus does not breathe before the moment of birth, it nevertheless practices some motions of breathing by exercising certain chest muscles. These movements slow down after the mother inhales just two cigarettes. Even when women quit smoking before pregnancy, their earlier smoking may still result in damage to the fetus, according to one extensive study.

Several researchers have investigated the effects of parental smoking on the health of children. One group of researchers conducted two telephone surveys of Detroit families to determine the relationship between children's respiratory illnesses and parental smoking habits. In both surveys, they found statistically significant relationships between the prevalence of children's respiratory inflammation and parental smoking habits. The body must rid itself of the toxins accumulated from the cigarette smoke. Respiratory inflammation, formation of mucus, etc., is one way of eliminating these toxins. This situation would become chronic if the parents continued to smoke in the child's presence.

Two researchers studied infant admissions to Hadassah Hospital in West Jerusalem and found a relationship between admissions for bronchitis and pneumonia in the first year of life and maternal smoking habits during pregnancy. A relationship between infant admissions and maternal smoking habits was demonstrable between the sixth and ninth months of infant life and was more pronounced during the winter months (when the effect of cigarette smoke on the indoor environment would be greatest).

The health of the fetus depends upon the health of the mother both during pregnancy and before conception. No one (not child or adult) can maintain health in a polluted environment.

[Home](#) > [Lesson 41 - Thanks For Not Smoking](#) > 9. Involuntary Smoking

## **9. Involuntary Smoking**

The effects of smoking on the smoker has been extensively studied, but the effects of tobacco smoke on nonsmokers has only recently received much attention. The chemical constituents found in an atmosphere filled with tobacco smoke are derived from two sources—mainstream and sidestream smoke. Mainstream smoke emerges from the tobacco product after being drawn through the tobacco during puffing. Sidestream smoke rises from the burning cone of tobacco. Mainstream and sidestream smoke contribute different concentrations of many substances to the atmosphere for several reasons. Different amounts of tobacco are consumed in the production of mainstream and sidestream smoke; the temperature of combustion differs for tobacco during puffing or while smouldering; and certain substances are partially absorbed from the mainstream smoke by the smoker.

A major concern about atmospheric contamination by cigarette smoke has been due to the production of significant levels of carbon monoxide. Cigarette smoking in poorly-ventilated, enclosed spaces may generate carbon monoxide levels above the acceptable 8-hour industrial exposure limits of 50 parts per million. Exposure to this level of carbon monoxide even for short periods of time has been shown to reduce significantly the exercise tolerance of some persons with symptomatic cardiovascular disease. There is also some evidence that prolonged exposure to this level of carbon monoxide in combination with a high-cholesterol diet can enhance experimental atherosclerosis in animals.

Sitting next to a smoker, a nonsmoker can be exposed to carbon monoxide levels more than twice as high as the maximum set for industry exposure. When nonsmokers leave a smoky environment, it takes hours for the carbon monoxide to leave their bodies. Unlike oxygen, which is breathed in and then out

again in minutes, carbon monoxide in the blood lasts for hours. After three or four hours, half of the excess carbon monoxide is still in the bloodstream. Not enough research has been done on other toxic substances inhaled by nonsmokers in the presence of smoke: formaldehyde, oxides of nitrogen, ammonia, cadmium, hydrogen cyanide, pyrene, and hundreds more.

In a room filled with tobacco smoke, people experience eye irritations and distress. Contamination and odors are immediately created by such elements in tobacco smoke as ammonia and pyridine. (Pyridine is a strong irritant produced when nicotine burns).

The contamination in smoky rooms is so intense that when someone lights a cigarette, cigar, or pipe in an air-conditioned place, the air-conditioning demands can jump as much as 600 percent. Another finding from air-conditioning research is that the human body attracts tobacco smoke. Burning tobacco creates a high-electrical potential, whereas the water-filled body has a low one; so smoke in a room gravitates and clings to people.

The effect of involuntary smoking on an individual is determined not only by the quantity and toxicity of the smoke-filled environment, but also largely by the characteristics of the individual. This does not mean that all are not poisoned by this smoke but the more toxic that an individual is, the more pronounced his symptoms will be upon being exposed to this smoke. The severity of possible effects range from minor eye and throat irritations experienced by most people in smoke-filled rooms, to the anginal attacks of some persons with cardiovascular disease.

A substantial proportion of the U.S. population suffers from chronic cardiovascular and pulmonary diseases due to generally unhealthful diet and other poor living habits. It is this segment of the population most seriously jeopardized by conditions found in involuntary smoking situations. It may be "the last straw that broke the camel's back." The body could not tolerate the extra toxins that were being imposed upon it.

Persons with chronic bronchitis and emphysema have considerable excess mortality under conditions of severe air pollution. In smoke-filled environments, levels of carbon monoxide and several other pollutants may be as high or higher than occur during air pollution emergencies. The effects of short-term exposure of persons with chronic obstructive bronchopulmonary disease to these conditions have not been evaluated.

[Home](#) > [Lesson 41 - Thanks For Not Smoking](#) > 10. Live Healthfully

## **10. Live Healthfully**

It is best to avoid smoke-filled rooms but it is not always possible. If you do occasionally find yourself in a situation where you must spend some time in smoky rooms, your body will be better able to eliminate the poisons encountered when you have been living healthfully. A vital, healthy body can deal with these situations as they arise as long as they are not on a daily basis. When you do not follow the laws of life and eat wrong food, get insufficient exercise and sleep, etc., the organism will be in a toxic and therefore weakened condition. It will be less able to eliminate added toxins and these new poisons will be added to those already present. Ill health will quickly follow.

A pure and healthy body is also quicker to detect unhealthful environments, and you will be much sooner aware of a dangerous situation. Electronic air purifiers are useful as they help eliminate the pollution from the air and therefore maintain a purer environment.

## 11. Eliminating The Smoking Habit

The safest, quickest, and surest way to eliminate the cigarette habit is through a fast. Many people have had great success through this method. A fast will enable your body to purify itself of much of the accumulated toxins from smoking and your health will greatly improve overall. This will be noticeable physically and mentally.

After the fast, your body will be so pure that the sight, smell, and taste of cigarettes will be repulsive to you. The next step is to begin a more healthful eating program. After you quit smoking, all your food will taste wonderful. When you break your fast on a nice juicy piece of watermelon or a delicious sweet orange, it will be the best food you have ever tasted! Now continue on a diet of mostly fruits with some vegetables and a small amount of nuts or seeds. Ideally, all of these foods should be eaten raw. You will feel so great that you will never want to smoke again!

## 12. Questions & Answers

### **Does a filter on the tip of a cigarette make them safer?**

No, there are no safe cigarettes. One study suggests that a smoker who switches from nonfilter to filter cigarettes may actually face an increased risk of coronary heart disease, primarily because of the higher carbon monoxide levels in smoke inhaled through filters. The paper surrounding the filter is relatively nonporous, and thus more carbon monoxide is passed on to the smoker than if no filter were present.

### **Have cigarettes with reduced tar and nicotine made any impact on the deleterious effects of smoking?**

Before the 1960s, many cigarettes contained 42 milligrams (mg.) of tar and 3 mg. of nicotine. By 1977, the average cigarette produced 16.6 mg. of tar and 1.09 mg. of nicotine. In a study of more than a million men and women, total death rates for those smoking cigarettes with reduced levels of tar and nicotine were lower than for those smoking brands with higher levels. However, death rates for those who smoked lower levels were still 30 to 75 percent above the rates for nonsmokers.

### **Do the harmful effects from cigarette smoking disappear immediately after quitting this habit?**

Many toxic substances from smoking accumulate in the blood and tissues. It takes a long time for the body to eliminate all of these harmful residues and much vital energy is required for this eliminative process. You can greatly assist this process, however, by going on a fast. Energy normally diverted into the digestive process can then be used for healing and repair.

### **What country produces the most tobacco?**

China is the leading tobacco-growing country producing 1,064,000 tons annually. The United States is second with 788,200 tons. It is sad to think that so much good land and energy is going into such a worthless crop. This same land could produce enough fruits and nuts to feed millions of people and the results would be beneficial, not harmful as they are

with the tobacco industry.

[Home](#) > [Lesson 41 - Thanks For Not Smoking](#) > Article #1: "A Small Fire at One End and a Big Fool at the Other" by Dr. Keki R. Sidhwa, N.D., D.O.

## **Article #1: "A Small Fire at One End and a Big Fool at the Other" by Dr. Keki R. Sidhwa, N.D., D.O.**

The title of this article, a quotation by G. B. Shaw, is an apt one for those who are slaves to smoking, for there is not a single thing about smoking in itself that is attractive, and many smokers actually dislike tobacco.

The man or woman who takes it up for one or the other reason, mainly psychological, soon acquires a mental habit which, in time, becomes a purely physical addiction. To say that the body craves the tobacco in any form is a gross insult to the inherent intelligence of the body cells. Tobacco contains 19 poisons, each one of them more damaging than the others, to the living cells. The body repels and abhors tobacco, as it does all poisons. The first puff of a cigarette by a nonsmoker shows how alert the body is in its defensive capacity. An all-out defensive action is started at the first contact of these poisons with the living organism and continues throughout the life of the smoker.

With each succeeding smoke, the defensive action of the living cells gets less and less until all vital activity of the cells concerned is reduced, and the organism is prostrated with exhaustion in deep stupor. The so-called "tolerance" of the smoker to his particular brand, like the pet sedative of the drug addict is but a mask hiding the true state of the living organism—complete enervation and exhaustion.

The natural resistance of the body is lowered and the body compensates by not reacting violently as when it was vital and vigorous. In other words, in precisely the proportion to which one becomes accustomed to the use of any poison, is his system depraved and his defensive powers reduced. The ability to smoke like a "man" without being sick is an evidence of cell weakness and physiological depravity. Hence the reason why a stronger and stronger dose is required before an addict actually gets acutely ill. To deprive him of his smoking means resting his system which as it gets stronger and stronger asserts its power in the form of active symptoms, in resistance against the cumulation of the drug, and this being disturbing and distressing like the usual fever or running nose, the smoker seems to crave his smoke, this hubby-bubby so that he can silence the waking sentinel again. The real effect of the next smoke is to renarcotize his nerves which can only cry out and reveal his true condition when they are no longer under the influence of the drug.

Some of the 19 poisons are the deadliest in their toxic effect, e.g. pyridine, nicotine, prussic acid, and carbon monoxide. Here is a short list of some of the most poisonous matter present in your particular manna from heaven.

Each one vies with another to be the first to show you the portals of the post-mortem existence somewhere beyond the clouds:

1. Carbon monoxide - prevents oxidation of blood.
2. Nicotine - half a drop is fatal.
3. Formic aldehyde - a strong irritant.
4. Carbolic acid - burns your throat.
5. Pyridine.
6. Furfural - responsible for "short windedness" and tremors.
7. Acrolein - degenerates the brain cells.

## 8. Saltpetre in the paper keeps the cigarette burning.

One cigarette causes a rise of 10-15 points in your blood pressure, i.e., increasing the work of your heart by 10%. Let alone its connection with lung cancers and hardening of the arteries (arteriosclerosis) smoking destroys inclination for marital embrace and the ability to copulate and to reproduce. Children of habitual smokers die early, are prematurely born, are stillborn, or are miscarriages.

Dr. Lucas, physician at Guy's Hospital, London, observed that testes dried up, atrophied, and shrunk to the size of a pea and sometimes also the sex organ. Tobacco impotence is steadily rising in the middle ages and 30% of women are frigid due to the tobacco habit. Women working in tobacco factories seldom have children. Yes, don't believe it now, but every smoke is a tiny drop of old age creeping on you unnoticed.

Fully three quarters of the cigarette smokers begin with the resolution of controlling their indulgence. But how many succeed? The answer is practically none of them, because poison demands more poison. Compromise plans won't work. All sorts are tried. A friend of mine conceived the idea of smoking so much a day and no more. It didn't work a week with him. Another wanted to smoke only in the evening after dinner and work. He stuck to it for a month and then gave it up as he was smoking more per evening than in the whole day previous to his embarking on this new compromise.

Yes, dear reader, they all fail, these so-called half measures. A few that succeed in rationing themselves thus, are relatively few and mostly those who "smoke" in order not to offend the boss or the company director—as if he really cared. And even if you are one of them, the difference between you and the smoker who goes the whole hog is only a matter of degree—the effect is still harmful and never beneficial, and it always will be.

Stand firm in an unqualified refusal to indulge in this bad habit! That is the only plan that will succeed. If you smoke to please, what about your nonsmoking friends! Keep your self-respect and your health at the same time.

Even the "tapering-off" plan when a smoker decides to quit, nearly always fails. There are two ways of getting into cold water for a swim—a headlong dive or a gradual wade in. Similarly, there are two ways of quitting tobacco— sudden stoppage and the tapering-off plan. If your heart is sound, the dive is your better course at the pool. The same applies for the tobacco—and especially if your heart is a bit *wanky*.

The wade-in system is an acceptance of failure, of self-doubt, and this attitude is really what defeats the one who wants to quit tobacco. Decision, not doubt, is what you need most. Why prolong the misery and play with temptation. "DIVE IN." It is the easier of the two in the long run. Your friends can't get at you with "have you had your quota today?" "One more today, two less tomorrow," etc.

Be firm and active—that's the only plan with smoking. Burn the bridges behind you; solemnly declare to yourself and others that you have quit once and for all and see the strain lift from you. See the relief, both mental and physical, in your eyes. Stick to it and a time will come when you will be proud of such an achievement. If you don't do it this way and now, you'll never be really free from it with ( any other plans, because the desire to quit is not strong enough.

An uncompromising decision, as above, will establish self-confidence and self-respect. The inconvenience will be much briefer and maybe a little more keener than on the one-by-one plan.

So there you have it all. Health for all is there for you too. So light your match and burn the cigarette at both ends. Then the fire burns and the fool with it too. The wise one stands back and smiles.

## Lesson 42 - Why Herbs Should Not Be Used

- [1. Introduction](#)
- [2. Questions & Answers](#)
- [Article #1: Why Herbs Are Harmful By Marti Fry](#)

### 1. Introduction

#### 1.1 The Myth Of Herbs

The woman was proudly showing me the inside of her medicine cabinet: "See? No pills, bottles of medicine, drugs or anything! I got rid of them all. I don't trust doctors or prescription medicines. I take only natural things."

She reached inside the cabinet and started pulling out capsules, tinctures, and powders. "This is peppermint oil," she told me. "I use it instead of an antacid for stomach upset. I've got these white willow bark pills for headaches so I won't need aspirin. I used to take tranquilizers, but now I can use these valerian root extracts to make me relaxed. I just use herbs now when I'm sick. I don't buy anything from a drugstore."

"That's too bad," I said.

She looked shocked. "Why? Because I don't buy drugs anymore?"

"No," I replied, "it's too bad you're still poisoning yourself with drugs—that's what all these herbs are. They may grow wild and naturally, but they're just as deadly as those pills with the unpronounceable names that the pharmacist sells you."

Many people can be convinced about the danger of prescription and over-the-counter drugs. They, or people they know, have often suffered side effects from drugs sold as cures. Yet these same people are often amazed that herbs too are equally useless and dangerous in restoring health.

Herbs have an undeserved reputation as "natural," "organic," "powerful," and "ancient." They grow out of the earth—they must be okay, these people reason. Such people may violently distrust bottles of medicines and pills sold by drugstores, but they will dutifully swallow capsule after capsule that contains the powdered remains of some unfamiliar plant.

This lesson is to help you explain to your friends and clients why herbs are *not* harmless; why they are *not* safe; why they should *not* be used. So many myths surround herbs, herb taking, and herbalists that the air must be cleared.

#### 1.2 What Is an Herb?

Most of us have a pretty good idea what an herb is. We generally think of some wild plant that tastes somewhat bad which is used in small amounts for some ailment or the other.

There may be some confusion, however, between herbs and vegetables, or other edible plants. For example, lettuce and salad vegetables are sometimes called "herbs." Parsley, which may be eaten occasionally with other vegetables, is classified as an herb. Animals, such as horses and cows, which eat primarily grass and greens are called herbivores or herb eaters.

Even the dictionary is no help in distinguishing herbs from vegetables. One definition of an herb is that it is a "seed plant which dies to the ground at the end of a season." This would mean that lettuce, cabbage, and indeed, almost all garden vegetables, could be classified as herbs. Another definition of an herb is that it's a "plant or plant part which is valued for its medicinal or savory properties."

Now we can see the two sides of an herb. It can either be a food (like a salad vegetable) or it can be a drug or a seasoning. For this lesson, an herb will not be considered as a food or as a salad vegetable. If it is safe to eat, a plant is classified as a food. If it has toxic, or "medicinal" properties, than it is classified as a drug.

This lesson is concerned chiefly with the herb as a drug. Mention will be made of herbs as foods, and whether they are proper nourishment for humans.

### **1.3 Warning: Herbs May Be Dangerous To Your Health!**

Some people may not believe that herbs can have any effect in keeping us well and healthy, but few people actually consider herbs to be harmful. Herbs are plants and grow naturally, and it seems that only people like the FDA and AMA have anything "bad" to say about these substances. But herbs are not only ineffective in producing health, they poison the body and may create serious complications in the user of such plants.

All herbs contain poisonous volatile oils and alkaloids. All herbs are fatal when taken in large enough doses. Even moderate amounts of certain herbs can cause vomiting, diarrhea, fever, headaches, and spontaneous abortions.

Many people do not realize that the herbs they take are in fact poisoning them. The reason? Herbs are taken in small amounts—usually small enough not to occasion a serious and painful reaction, but still enough to cause the body to react radically and expeditiously to eliminate them. These reactions by the body to eliminate the toxic substances found in herbs are taken as "proof" by herbalists that their potions are doing their job. A job is being done, all right, but the results are not always as advertised.

If herbs are not harmful, why must they be taken in such small amounts? Like pepper, spices, and condiments, herbs cannot be ingested in amounts larger than a tablespoon or so. Even more telling is the taste of herbs themselves. Almost without exception, herbs are bitter, strong, and foul tasting. This is a warning to the body not to eat such substances.

Very few people would chew and swallow a mouthful of an herb. They couldn't choke such a strong and bad tasting substance down. Instead, they usually grind and powder the herb until it can be stuffed into a capsule and slipped past the sense of taste which is the body's guardian against poisons and drugs.

If a food or substance cannot be enjoyed—if it does not have a pleasant taste—then it should never be eaten or ingested. Even a perverted sense of taste can protect a person from the foul poisons found in herbs. Yet with pills, capsules, and infusions, the herbalists have found ways to sneak a plant into the body that it would never relish or desire normally.

Still, people who are attracted to a natural way of life and diet defend herbs and their use. Maybe we should ask the question:

### **1.4 Are Herbs "Natural"?**

Of course herbs are natural. They grow in every part of the world without cultivation. Unlike most fruits and vegetables, herbs have not been altered through selective planting or breeding. The herbs growing today are much the same as those that grew five thousand years ago. No one can argue that herbs are not natural plants. But, are they natural for man to eat and use?

The argument for herbs has been that since they grow everywhere, they must be good for something. We should be able to use these wild plants since they must be provided for us by nature or by a divine being.

One of the best known herbalists in America answers the question "why use herbs?" as follows:

"Herbs are nature's remedies, and they have been put here by an all-wise Creator. There is an herb for every disease that a human body can be afflicted with. Herbs were mentioned in the Bible, and much has been written about them all through history."

In the words of Dr. Herbert M. Shelton: "Such an argument is specious, false, unscientific, and absurd. It is not sustained by theory nor by results, neither by logic, or analogy, nor by experiment or experience."

Simply because a plant grows naturally does not mean that it was intended or ordained by a divine being (or nature) for our use. A great many plants grow all around us that are rank poisons. The tobacco plant has large and lovely green leaves. It certainly looks as if it would make a wonderful salad food. If you ate a salad of tobacco leaves, you would not live to regret it.

Animals in the wild refuse to eat many of the plants growing around them. Toxins and poisons are to be found in plants, just as are vitamins, minerals, amino acids, and so on. As Dr. Shelton has observed, "Many of the products of nature are unfit for the entrance into the human body."

If so many herbs taste so foul and have such detrimental effects on the body, then we might ask how the herbal practice ever got started in the first place.

## **1.5 The Origins of Herbal Drugging Practices**

The herbalists and the medical profession which also derives many of its drugs from herbs have justified the use of such poisons by pointing to the practices of antiquity and primitive tribes.

"For thousands of years," one herbalist writes in his correspondence course, "herbs have been used in the treatment of disease. From the time of King Solomon, who was reputed to be the wisest man of his time, on down to Hippocrates, Galen, and through the Middle Ages to the present time, there have always been great and famous herbologists or botanical physicians."

We could also add that there have also always been fools and unwitting dupes who have fallen prey to this mumbo-jumbo about the "glorious" history of herbs.

The romantic picture of remote and ancient men who searched the landscape for herbs to cure mankind is a popular, but false one. Always the herbalist is glorified as a wise magic man that could divine the true nature of the wild plants around him. Actually, nothing could be farther from the truth.

The first herbalists were superstitious witch doctors and shamans who used these plants not for any healing virtues, but for magic rituals and ceremonies for sex and power. The herbs were used right along with snake eyes and frog skins to make magic potions. They were not used as curative agents, but as magical talismans.

Medical historians and students of herbology, however, seek to justify their drugging practices by pointing to the past uses of herbs by primitives as an "instinctive" use of such plants. Neither man nor animals will "instinctively" eat a plant that is full of poisons and toxins. It is very doubtful that any person living in nature would desire to eat a foul, bitter plant that causes the body to react vigorously to eliminate it.

The truth is that herbology, like circumcision, is a dark age ritual that has unjustifiably survived. The primitives had no more success when they used herbs for medical curing than they did when they performed circumcision on their youths to prevent masturbation, or whatever. Both herbs and circumcision are barbaric practices that are still with us in spite of an "enlightened" twentieth century.

The romanticizing of herbs and their effects as being "natural" or "primitive" and therefore established and accepted is a dangerous lie. Herbs are drugs and poisons. They cure nothing.

## 1.6 Why Herbs Can't "Cure"

People who believe in the curative powers of herbs think that any disease or ailment can be relieved by the ingestion of the proper herbs in the correct amounts. Some herbs are to be boiled and steeped.

Others need grinding and powdering. Some herbs are to be taken in combination with other herbs.

Some herbs must be taken alone to "work" properly.

There are dozens and dozens of books that list herbal formulas for every conceivable illness. No matter what bothers us, the herbalists have a list of plants we can take to "cure" ourselves. So simple and so appealing.

Every herb has its own healing properties, its own virtues, its own potencies. Reading a book on herbs is like reading an encyclopedia of diseases and cures. No wonder herbology is so seductive. We need do nothing to change our living habits to regain our health; we only need to take this or that herb in some amount or combination.

There is no curing power in any herb. All healing power resides in the tissues of the individual. An herb can cure nothing. Herbs, like all drugs and poisons, are inert substances. They perform no actions. They stimulate no healing. They remove no cause of illness. They cannot rebuild the body. They are inactive and incapable of initiating any constructive action within the body.

But herbs do "work" in a certain way. When they are introduced into the body, the vital organism attempts to expel these poisons as quickly as possible. The body protects itself from drugging and poisoning, whether these poisons come from a pharmacist's shelf or from nature.

These protective efforts by the body are misinterpreted as beneficial actions of the herbs. For example, the herb called mandrake has long been used for liver ailments. When ingested, mandrake causes vomiting, purging, and griping. The herbalists view these reactions as beneficial; they say that the mandrake is causing the body to clean itself out.

What is actually occurring is that the body is making a heroic effort to expel the mandrake by any avenue possible. The purging and griping are signs of a vital organism trying to eject a poisonous substance. It is not a "curing crisis" brought on by the herb.

Different herbs may occasion different bodily reactions. Fevers, sweating, diarrhea, increased or decreased circulation are all signs of a body trying to eliminate herbal toxins and are not indications that an herb is working some cure or the other.

## 1.7 Can Herbs Help At All?

The use of herbs is often defended because they are not as strong as chemically-derived medicines. In other words, they seem to do less harm than prescription drugs. But is this really true? Are herbs the lesser of two evils? And is there ever any reason they should be employed?

Even if herbs possessed no toxic or poisonous properties, they would still be dangerous. Why? Because the use of herbs, or any "curing" agent, simply perpetuates the ignorance that enslaves so many people.

Herbology promotes the idea of a "cure." As such, it does nothing to remove the true causes of disease and illness. Herbs deceive people. Many people think that by swallowing some plant or the other, they can improve their health. Such thinking can be dangerous.

For example, high-blood pressure is a very common ailment among Americans because of the tremendous amounts of salt they eat in their heavy meat and processed food diet. A vegetable alkaloid found in certain herbs called *reserpine* has been used to reduce blood pressure. Garlic, long touted as a wonder herb, is also a supposedly effective agent in reducing blood pressure.

What sometimes occurs is that people with high-blood pressure ingest garlic and other herbs to correct this condition. At the same time, however, they continue with their old diet and eat large amounts of salt.

When this happens, the symptom of high-blood pressure is hidden by the symptoms of the herbal poisoning. At the same time, the old habits and diet that kept the blood pressure high are not modified. The high-blood pressure is simply a signal by the body that something is wrong—like diet or lifestyle. By taking an herb for this symptom, nothing positive is being done; indeed, a poison has just been added to the body which it now must eliminate.

Herb taking, then, is simply symptom masking. In other words, a symptom of a diseased or disordered body is hidden by the eliminative efforts of the body to rid itself of the herbal toxins. The causes of the initial symptom remain, and indeed, continue the destruction of the body.

Garlic and other herbs may mask *one* symptom of a high-salt diet, but they can do nothing about the kidney damage and cellular destruction that also accompanies salt eating.

All pill and drug taking is dangerously deceptive, whether the drug comes from a plant or from a factory. The symptom-ridding approach to health is a short-ended one, and the bills for a disease-producing lifestyle always come due. Herbs and the symptom-repressing attitude toward health only deceive and delude the true health seeker.

## **1.8 Are Herbs Good For Food Supplements?**

Not only are herbs promoted as cures and remedies, but they are often given as dietary supplements. Herbs often have a high concentration of minerals (usually iron, calcium, and trace elements.) Some have a high vitamin C content as well.

Because of this concentration of nutrients, herbs are also used as nutritional supplements. For example, there are herbal formulas that are reputed to have the proper mineral combination for building bones or increasing the red corpuscle content of the blood. Many people who dislike supplements made in a laboratory will use these herbal formulas to "improve" their diet.

In this case, the herb is being used as a concentrated food instead of a "medicinal cure." But can such a practice be justified?

The human body can only utilize a certain amount of vitamins, minerals, and other nutrients during a given time period. Any excessive amounts of nutrients are eliminated by the body in the urine and feces. For example, brewer's yeast is sometimes used in the diet for a high B-vitamin supplement. The body can only use a limited amount of these B-vitamins; the rest comes out in the urine.

The high and concentrated amounts of nutrients in most herbs cannot be totally used by the body. Only so much of a mineral or vitamin can be used, and the excess in the herbs must be eliminated. Taking in nutrients in excess of the body's needs is not "insurance"; instead, the body is burdened by minerals which are in excess of its needs.

Fortunately, most natural foods suited to man's physiology (like fruits, vegetables, nuts, and seeds) are well-balanced nutritionally. Herbs, however, do not have a balanced array of nutrients for human needs because they are not properly a food for man to eat.

Our vitamin and mineral requirements can be more than met with a diet of natural and unprocessed fruits and vegetables. Herbs are not needed food supplements, and indeed, they may serve as a dangerous substitute for a proper diet of fresh and wholesome foods.

Then, too, you must remember that along with any minerals or vitamins the herb may possess are also alkaloids and poisons that the body cannot healthily metabolize. Herbs are not a safe supplement. In fact, no supplement is safe because all such unbalanced additions to the diet disrupt the body's metabolism and force it to eliminate the unneeded substances and excesses.

## **1.9 Why Herbs Appear To Work**

Even after people have been told about the harmful effects of herb taking, they often persist in the

practice because they insist that the herbs are working and helping them. An elderly man of about ninety has dutifully swallowed a capsule containing an herbal laxative every day for the past several years. "It keeps me regular," is his only comment and justification for the herb-taking habit.

Herbs do have an *effect* on the human organism. There can be no question about that. When certain herbs are taken, headaches do disappear and constipation seems to vanish. Are the herbs "working" as the herbalists would have us believe?

In a discussion on herbs and their seeming ability to "cure," Dr. Shelton has stated:

"Only poisonous herbs are thought to have medicinal qualities. If an herbal substance does not occasion actions of expulsion and resistance when taken into the body or applied to it, it is not vested with any power to cure. If the body ejects the herb by vomiting, diarrhea, diuresis, or diaphoresis, and this is accompanied by some pain and discomfort, then the herb is regarded as beneficial and it is used to "work." If the patient then recovers in spite of the herb taking, full credit for recovery is given to the poisonous plant, and the *self-healing power of the body* is completely ignored.

Shelton and other Hygienists have stated that for any substance to have a so-called medicinal effect, like herbs do, it must be a poison. This is because the alleged medicinal effects of a substance are nothing more than the efforts of the body to expel and resist poisons. Herbs and other drugs, instead of being digested and utilized by the body, are expelled.

What does all of this mean? Let's take a simple case where an herb appears to do some work. Peppermint, a rather mild herb by most standards, is sometimes used to "cure" a headache by herbalists. Your head hurts, so you drink a cup of peppermint tea. Your head stops hurting. Did the peppermint work?

Yes and no. Most headaches are caused by swelling of the intracranial blood vessels around the scalp. These blood vessels swell because of toxic matter in the bloodstream and body, and they then press against sensitive nerves. When peppermint is taken, the body recognizes its oils as harmful. Circulation is rapidly increased by the body and the heart speeds up. At this point, the body is attempting to eliminate the peppermint toxins as quickly as possible by increasing circulation so elimination can proceed.

The increase in circulation, due to the toxic nature of the peppermint oils, has an effect on the swollen blood vessels in the head. The vessels are dilated so that the circulation can proceed rapidly and the peppermint poison can be eliminated. As a side result, the headache disappears temporarily.

So is the headache cured, and did the peppermint work? No, the body did all the work. It worked to eliminate a poison, and these efforts also masked the symptom of a toxic body—in this case, the headache.

The cause of the headache—toxicosis—was not removed by the peppermint. The conditions that brought on the toxicosis—poor diet and lifestyle habits—were not improved by the herb. The headache may have disappeared, but the underlying cause remains. This is the case with all herbs—symptoms are depressed by the eliminative actions of the body which are directed toward the herb.

## **1.10 Living an Herb-Free Life**

Almost without exception, herbs have been used to treat the sick. They are rarely used as food, although occasionally herbs have been used as seasonings or condiments. A lifestyle without herbs is both easy and healthy.

First, you should realize that most people resort to herbs in an effort to cure themselves of some illness. As a student of Life Science, you already know that there can be no "cure" for any disease. Poor health can only be improved by healthful living practices—not through drugging, treatments, or cures. The proper response to an illness is a complete physiological rest—fasting, if possible. Following a complete

or modified fasting regimen, the individual should adopt a healthy diet of primarily uncooked fruits and vegetables which are eaten in as whole a state as possible.

Herbs, and other drugging agents, are often used by people who desire a quick "fix" of their problems without any change in their lifestyle. Since it is an unhealthy lifestyle which created the disease in the first place, this approach always fails. The use of herbs may produce different symptoms or masked symptoms, but the herbs themselves cannot remove the underlying cause of the symptoms.

Therefore, to live a life without herbs, we must realize that their use in times of sickness is deceptive. We must understand that total health can only be regained by fasting, proper diet, and a healthy lifestyle. Herbs have no power and no capacity to effect these changes in our lives.

Swallowing herbs is like swallowing any other pill or drug. The fact that they grow naturally does not give them any extra or safe curative properties. Indeed, all curative properties reside within the human organism. No outside agent, *including herbs, can instigate any healing capabilities of the body.*

Besides medicine, then, what else are herbs used for? Some people use them as food supplements. But if you are following the biologically-correct diet of chiefly raw fruits, vegetables, nuts, seeds, and sprouts, then there is never a need for herbal supplements or any type of nutritive additive. Many people are wont to blame their health problems on some deficiency or the other, which they then seek to correct by herbal or chemical supplements.

In reality, most illnesses are not caused by any deficiency, but rather by a sufficiency, or excess, of toxic materials in the body. Taking supplements merely adds to this toxic level, and no causes of the illness are removed.

Finally, herbs are sometimes part of a meal. The culinary herbs, such as garlic, onion, parsley, rosemary, cumin seed, caraway seed, and so on are probably the most common herbs used in most diets. Let's look at these herbs and seasonings in closer detail to see how we can also live without them.

## **1.11 Herbs That Taste Good?**

Herbs that are foul and bitter tasting, as are most of the medicinal herbs, can be easily explained as unsuitable for the human dietary. Who would want to eat them anyway? Other herbs, however, have enjoyed a reputation as seasonings and flavorings in cooking and food preparation. Since this is where herbs are often used in everyday living, we should understand their use better. First, almost every herb used as food in the diet is done so as a seasoning or flavoring for cooked food. Few people desire to eat rosemary or caraway seeds with their raw vegetables. Most such herbs, then, are used to season cooked foods.

Why are seasonings or herbs used in cooked foods? Because the natural flavors and taste have been destroyed in the cooking process. The aromatic herbs are simply used to disguise the insipid taste of the cooked foods.

A predominantly raw food diet does not need aromatic or culinary herbs to "spark" up the flavors. Only in cooking have these herbs gained a foothold. But are they harmless seasonings?

No, because many of the herbs used as seasonings have strong oils and alkaloids that disrupt digestion. Ginger, for example, causes the digestive system to hurry the food through before being completely digested. Thus, these seasoning herbs have gained an undeserved reputation as "digestive aids." Instead of aiding digestion, their use occasions the body to rapidly expel them along with the food they seasoned.

What about some herbs that are relished in a raw state, such as garlic, onions, parsley, and so on? In general, these types of herbs are not needed and may prove harmful to the organism. Garlic and onions, two of the most popular flavoring herbs, are full of noxious toxins, like mustard oil and allicin. Parsley is also a strong herb whose use can overstimulate the kidneys. It is a very concentrated green herb which

should probably not be a part of the regular diet.

The cooking and seasoning herbs are not harmless additions to the diet as is popularly believed. Their use disrupts digestion and places an added load on the eliminative system. They are used chiefly to flavor and spice up foods that are probably best not eaten anyway (that is, overcooked foods, meats, and so forth). A diet of fresh fruits and vegetables require no seasonings, herbal or otherwise.

[Home](#) > [Lesson 42 - Why Herbs Should Not Be Used](#) > 2. Questions & Answers

## 2. Questions & Answers

**Aren't herbs still better than taking prescription drugs? I used to take digitalis for my weak heart, and now I use a plant called foxglove.**

Many drugs sold by pharmaceutical companies are often nothing more than a laboratory extract from a plant or herb. The digitalis you used to take came from the foxglove plant you now use. What's the difference? Both still have the same sort of toxin that occasions an increase in circulation and a rapid heartbeat.

Herbs are drugs. When you take an herb, it's like swallowing a pill or spoonful of medicine. The only difference is in the package they come in. Herbs come in familiar, "organic" looking packages—the plant itself. Medicine comes in plastic bottles. The contents, as far as the toxic effects, are about identical.

This is the most difficult point to get across to people that use herbs. Simply because something deadly comes in a form that looks organic and natural does not make it any less deadly.

**Okay, you say herbs don't work. But when I take some white willow bark capsules for a headache, my head stops hurting and I can go about with my work. Sorry, but pain relief is where it's at as far as I'm concerned.**

All pain, including mild headache, is the body's signal that unhealthy living practices are being engaged in. For instance, in your case you get a headache at work, so you take some herb and go on with your work. That's the danger in herbs.

Taking an herb may cause a painful symptom to disappear, but the cause of that symptom (perhaps in your case, your working conditions) will remain.

Agreed, pain relief is "where, it's at," but you should ask yourself, why am I feeling pain? Pain is never a natural condition. Using unnatural methods, such as dosing yourself with herbs, is a dangerous response to the pain signal.

**I agree with you about most herbs, like goldenseal and so on that just taste terrible. But some herbs taste good, and I don't see why we can eat them without food.**

Anything you take into your body, with the exception of water, is either a food or a poison. Either your body can use it as healthy nourishment, or it must try to eliminate it as a toxin. Herbs are often borderline cases between a food and a poison. The majority of herbs have so many harmful alkaloids that any nutritional benefit they might contain is negated.

True, some herbs such as basil, comfrey, spearmint, and so on may taste pleasant. But in what amounts? Even the most dedicated basil or parsley or rosemary lover would not want to chew up a whole mouthful of their favorite herb. Why? Because even these "mild" herbs are extremely high in essential oils that can irritate the organism. While such herbs are not as dangerous as the stronger acting "medicinal" herbs, there is no need for them in the proper diet.

[Home](#) > [Lesson 42 - Why Herbs Should Not Be Used](#) > Article #1: Why Herbs Are Harmful By Marti Fry

### **Article #1: Why Herbs Are Harmful By Marti Fry**

The term "herb" has two definitions. The first is simply a "seed-producing annual, biennial, or perennial that does not develop persistent woody tissue but dies down at the end of a growing season." According to this definition, the various vegetables used in moderation on a healthful diet are herbs—celery, lettuce, bok choy, kale and other greens; broccoli; cauliflower; etc.

While relatively wholesome vegetables are herbs, the term "herb" really refers to a plant and not to a food. Let me clarify: when you eat a "vegetable," you're eating the stems, leaves, or flowers of a plant. Those stems, leaves and flowers that contain only very minute amounts of toxins are consumed as vegetables on the healthful (Hygienic) diet. But the poisonous (toxic) parts of plants are not consumed. For example we do not eat tomato plants or cucumber plants. Being of the deadly nightshade family, tomato plants are highly toxic. But we do eat the fruits of some plants, even though the leaves, stems, and flowers of the plant itself may be toxic.

One final comment about the eating of the herbs we call vegetables: These should definitely not comprise a major portion of a healthful diet, partly because of the minute amounts of toxins they do contain, and partly because they do not adequately meet our need for carbohydrates (for energy). Vegetables do contain carbohydrates, but they are mostly in the form of the carbohydrate cellulose, which humans, as frugivores, are unable to digest. Herbivores, with their four stomachs and special enzymes for breaking down grasses and other herbs, are, of course, fully capable of obtaining ample energy (carbohydrates) from herbs. Horses and cows are two notable examples of herbivores.

Frugivores, such as humans, are equipped to obtain energy primarily from the sugars in fruits. Our physiology and anatomy is such that we are capable of picking fruits, as well as masticating, digesting, and appropriating them with ease and efficiency. They contain all the nutrients we need—from vitamins and minerals, to proteins, fats and, of course, carbohydrates.

But, like the other frugivores (monkeys, apes, orangutans, etc.) humans can add relatively small amounts of vegetables to their fruitarian diet with benefit. The indigestible cellulose is simply passed through in the same form as it was ingested, and nutrients are utilized from the fleshy portion that is extracted during the chewing process.

The cellulose from vegetables is not, however, essential for human health. If we eat a hygienic diet we do not need large amounts of fiber (roughage) to keep our colon healthy. The important consideration for colon health is the same as the consideration for the health of every other organ and part of the body—freedom from toxins and toxic buildup. A pure (toxin-free) body is the result of healthful living and eating practices and not from the ingestion of any particular food, herb, or class of foods. Enemas, juices, roughage, and other substances or practices do not result in a pure (unpolluted) healthy body. Health is the normal state unless toxicosis and disease are caused by anti-vital practices and foods.

## The Second Definition of "Herb"

The second definition of "herb" is: "a plant or plant part valued for its medicinal, savory, or aromatic qualities." This means that an "herb" is used either as a "medicine" (drug), or as a seasoning, perfume, or insect repellent, etc. Herbs are used, not for their nutritional values (their vitamin, mineral, protein, fat, or carbohydrate content), but for their toxic ("medicinal") components. For example, onions and garlic are used for their mustard oil and allicin content. Both of these toxic substances are, indigestible and incapable of causing diseases to disappear or health to be restored. The toxic component of aloe vera is the glycoside aloin; in sassafras it's safrole; and in the Indian snake root, it's the alkaloid reserpine.

The poisonous substances in herbs are causes of body toxicity and diseases. Toxins or poisons are anti-health, no matter what their source. We cannot be drugged into health, whether the drug (toxin) is from herbs or from a pharmaceutical company—or even from cooked foods, processed foods, incompatible food combinations, or excess food, etc. Drugs, "medicines," and herbs are alike in that they all cause disease and are incapable of "curing." You may obtain a temporary feeling of well-being through their use, and disease symptoms may cease for a time. But appearances can be deceiving.

The human body is the only entity capable of healing, and no substance or procedure can speed up or assist healing in any way. There is no such thing as "curing" or "medicines." "Medical" interference in attempts at "curing" is just that—interference. The body heals itself, purifies itself, and repairs damages from injuries caused by toxins best under the condition of a fast, in which complete rest is obtained.

Rest is needed during healing because the body must recuperate as much nerve energy as possible, thus increasing its vitality, in order to have the energy it needs to conduct the disease process. Disease is a body process of toxin elimination. It is not caused by "germs" or viruses, but is necessitated by the accumulation of toxins within the body.

The body institutes the disease process, and drugs and herbs sabotage the body's efforts by posing another threat to the body besides the toxins it was eliminating through the disease process. Being capable of handling only a limited amount of toxic matters at a time, the body temporarily halts the disease process and devotes its energies to ejecting the new offending substance.

If the drug or herb is particularly toxic; if it's given in a large dose relative to the subject's vitality (supply of nerve energy); or if the subject is particularly low in vitality, the result of its administration may be almost complete cessation of the disease process. The body may be temporarily incapable of ejecting the toxins accumulated in the body or those in the drug or herb.

In this case, the body, though it may be showing no or few *symptoms* of disease, is more diseased than before the drug or herb was administered. That is, the body is more toxic—more diseased. When vitality is regained, in time, the organism will again institute the disease process in an effort to expel its toxic burden. If herbs or drugs are again administered, the body begins to suffer more and more from the injuries inflicted by the irritating poisonous toxins within. Various diseases, including arthritis, ulcers, cancers, and others, ensue.

## Herbs Are Dangerous

No matter how herbs are used or what they're used as (expectorants, stimulants, astringents, etc.) they always, without exception, add to the body's toxic load, which is the real disease. The disease process is simply a body activity for expelling toxins so they will not injure the body and thus impede its functions.

In addition, herbs, like other drugs, temporarily, at least, give the *illusion* of health in some cases. Thus a person is not inclined to institute correct living practices so as to not cause further disease or to remove the practices and habits that cause disease. The result? More disease and continued disease, which is the opposite of the herbologist's intentions, if he is truly health-minded and not simply money-oriented.

## **What To Do**

If you are an herb doctor, may I suggest you consider becoming a Natural Hygiene counselor instead. If you use herbs, I suggest you discontinue their use and, instead, institute healthful practices while simultaneously eliminating all unwholesome (drug) practices. My own experiences, as well as the experiences of many Natural Hygienists, verify the efficaciousness of this advice. If you are not yet willing to accept what I have said and what has been written elsewhere in the Life Science publications, study some more Hygienic literature.

And remember: health results only from healthful living. You cannot "make up for" any unhealthful practices by the use of herbs, or by the use of any other substances or practices. There are no magic potions and no shortcuts. And, after all, the path to health is *not* a hard road to follow anyway!

## Lesson 43 - Cooking Our Food

### 1. A Statement Of Purpose

In the foreward to a popular book on cooking we find these words: "Cooking is not a particularly difficult art, and the more you cook and learn about cooking, the more sense it makes." It is the purpose of this lesson to show you that cooking makes no sense whatsoever in any lifestyle designed either to build health or to maintain it. In fact, to a hygienist, cooking is the way of the devil rather than the way of an intelligent person, one knowledgeable about the capacities and limitations of the human body and of what is entailed in the proper preparation of food so that it will be capable of maintaining a high level of health throughout an extended life span.

By far the most important cause of ill health in man is his many and habitual dietetic errors of one kind or another, the immediate results of which are not felt and intelligently evaluated. We can abuse our digestive organs for years and feel no pain. We can create problems for our kidneys by overconsumption of protein for years and feel no pain. However, the time comes when these organs rebel and we become intelligently aware of a diseased condition which is manifested either in the damaged organ itself or in some other place remote from it which has been made diseased through malnutrition or by the presence of irritating toxic metabolic wastes accumulated beyond the body's overworked eliminative powers.

It is the gradual erosion of health by the more or less constant bombardment by erroneous eating practices which, in most cases, is responsible for the destruction of health. At the present time, after hundreds of generations of experiences with a diet of cooked breads, cooked meats and fats, in actual defiance of the body's inability to process or use them, we see refined white sugars and syrups used to sweeten just about all canned, frozen and cooked vegetables and fruits; in these "modern" times, we have badly prepared meals cooked to perfection but lacking all properties essential to life; we are confronted on all sides with malnutrition and disease as evidenced by the fact that over 99 percent of the populace has dental caries, 70 to 80 percent are overweight; spines curve and vitality weakens; more and more people wear eye glasses due to impaired vision; at least 70 percent of the people are constipated, and we witness a rising and alarming incidence of cancer and other horrendous degenerative diseases. We find ourselves fighting an almost hopeless war on misery and disease which we ourselves have created.

Here in Tucson we have recently been placed on notice that hospital "care" of the sick is expected to rise another twenty percent during the coming year. This is an age of despair and of fear, particularly among the elderly who are faced with a future which they believe they cannot control. We are convinced that this country could witness a metamorphosis in the health of its people if we could all adopt a manner of

living and eating which is sane and biologically sound; if we could convince everyone to adopt a non-stimulating uncooked diet, one which contains the necessary life elements in the right quantity and in the correct proportions and in the highest degree of organization, these attributes being found only in nature's food packages, ready for our appropriation when eaten just as provided for our use, uncooked. Otto Carque tells us that we should always be guided in the selection and preparation of our foods by the fact that we cannot improve on nature, and that all foods which we enjoy in their natural state are the foods which are best adapted for maintaining health. We feel that what is most needed is self-control and knowledge of how to live according to biological need. The purpose of this lesson then is to enlarge our understanding of the benefits to be accrued by the consumption of uncooked food and to understand why health can be, so manifestly improved and in a relatively short time on an all-raw diet.

[Home](#) > [Lesson 43 - Cooking Our Food](#) > 2. What is Cookery?

## 2. What is Cookery?

Cookery is defined as the art and science of preparing food for eating by the application of heat. The various preliminary methods by means of which food is prepared for the particular recipe or procedure are also usually included in the term. We refer to such prior practices as cleaning and removing certain inedible portions. Other preparatory processes as cutting, shredding, salting, addition of spices, methods of mixing and shaping, and so on are also included. In this discussion we will concern ourselves mainly with the effects produced by the application of heat to foods with little consideration being given to preparation procedures and methods since most of these are commonly recognized as being destructive of nutrient values to some degree.

### 2.1 Historical Insights on Cooking

In the civilized world, after due consideration of the state of one's health, food is probably the single most factor of living that outranks all other aspects of living in commanding mankind's attention. The various methods of preparing and eating food are extolled as arts and can give one a cultural image of the peoples of the world. We can often get a better understanding of people when we understand their cookery. Epidemiological studies reveal that much can also be learned about the status of their health by studying what they eat and how their food is prepared.

As is stated in *Cuisines of the Western World* authored by Elizabeth Gordon and published by Golden Press (The Heart Corporation, N.Y., 1965), the cuisines of various cultures have been cross-pollinated by explorers, by wars, by colonization, by immigrants, by religious customs and, in more modern times, by tourism. Only a handful of cultures have remained isolated. Gordon reflects how what people eat and how they prepare it is often determined by their climate, their agriculture, their wealth, their social system, who they conquered or whom they were themselves conquered by. The cookery itself reflects both folk wisdom and the culture of the more affluent, past and present.

It is doubtful if we will ever be able to trace the origins of cooking fully and completely. We know that the practice is deeply rooted in ancient times. Probably as populations grew and tribes were compelled to seek nourishment in more remote and less populated areas, people were forced by hunger to eat quail, duck and other small birds, at first in the raw state, then later salted, and still later boiled or roasted over an open fire. Due to the fact that grains were easily grown, kept well and were easily transported, they were called into use early in history as human food. Herodotus records that the early Egyptians were among the first to till the soil and that they ate largely of fruits and vegetables, and these uncooked. It is said that they also were skilled in the baking of a great variety of breads. However, it appears that the

early Romans were among the first really to popularize cooking food. They also were skilled bakers of bread. Onions, garlic and leeks were commonly in use in both countries as vegetables but the members of the priesthood were forbidden to use them. Legumes were also on the prohibited list.

The peoples living in those countries bordering on seas and oceans soon learned to fish and many varieties of fish became staple articles of foods among such peoples as the Greeks and Italians. Arcestratus, a Greek poet of the 4th century, tells of boiling fish in a mixture of oil and wine and spicing it with fragrant herbs. The Greeks introduced other slaughtered animals to the bill of fare, including the ox, sheep, pigs, lambs and goats. Roast lamb was especially prized in Greece and in other Mediterranean cultures, just as it is now. The Greeks also used a wide variety of vegetables which grew in the friendly warm climate, vegetables such as cabbage, leeks, onions and lettuce. Sesame seeds, figs, olives and nuts grew in abundance and were eaten not only raw but also cooked in a wide variety of cakes and breads.

The early Romans had access to an even larger variety of food. The peasant classes subsisted largely on grains and lentils cooked with a few vegetables and on the wild fruit of the country. Lentil soup and stews are still popular in many parts of Italy today. After the conquest of Greece the wealthier class of Romans came to know and enjoy an elaborate array of foods well-cooked in olive oil and adorned with fancy gourmet sauces which were well-seasoned by spices, especially garlic. Because of the heat, foods, especially meats, were subject to rapid decay. The cooking sauces and the seasonings helped to disguise the foul odors and to make the repugnant taste of decayed meat more palatable, so their use rapidly became not only tolerated but actually prized.

In France and Italy and also in more northern countries, the milk provided by horse mares, goats and cows was allowed to sour and curdle and then often stored in caves during times of plenty and brought out for human consumption months and years later in times of scarcity. Thus, was born the fine art of cheese-making.

In the dawn of civilization the British and their Teutonic invaders apparently paid little attention to cooking but by the time the Middle Ages had arrived, cooking was considered a fine art. The same can also be said of France and Spain who early on adopted Italian methods with suitable variations developing according to climate and availability of materials. The French, of course, later became famous for their tantalizing sauces and their use of wines, and more delicate herbs than are commonly used in either Spain or Italy.

Many of the ancient cooking practices influence the "art" in Italy to this day. Just a few years ago we travelled on an Italian freighter from Long Beach Harbor in California to Trieste, Italy. Thanksgiving Day came while we were yet on the high seas and in honor of the only Americans on board, ourselves, the chef prepared a Thanksgiving turkey. He personally conducted the bird to the dining room. The chef, in typical chef's attire including his grand hat, laid it before us with a flourish and a magnificent bow. There the turkey lay, reposing on a huge platter, adorned with rosy tinted crabapples and smelling to the high heaven of garlic! In honor of the American holiday, Dr. Robert was asked to carve the bird and to serve the plates for the officers and other passengers on board. We all ate of the bird while the proud chef looked on eagerly noting our responses to his culinary efforts. Never have we eaten of such a bird and never will we again! It was stuffed with olives and spiced breads, it dripped with olive oil and reeked of garlic. The sharp spices burned the delicate linings of our alimentary tracts and we tasted that bird for hours after the feast. But, we never let on and the crew's joy was complete as they watched us eat of that unique product of the ship's culinary art.

In the Far East, rice, fish and wild fruits became staple articles of diet. It is said that Confucious (551-479 B.C.) was the first gourmet in China setting forth standards for ingredients and methods to be followed. These were, of course, changed as the population increased and wandered. Millet was the popular grain in northern China, With rice being the staple in most other parts of eastern and southern Asia. Spices were widely used, especially in the more southern regions where heat rapidly caused onset of decay.

Thus we can see that early cookery was more or less forced on the people both by the scarcity of food at certain times of the year and by the lack of refrigeration. As time went on, the palate became more and more accustomed to cooked foods and probably in direct proportion to the quantity of cooked food consumed, the health of the people deteriorated.

In America where the land was largely virgin and offered up a wide variety of foods of all kinds, the early settlers became accustomed to eating enormously of many dishes and courses. Graham relates how the dockworkers of Greece and Spain in the middle of the last century who ate simple fare consisting largely of coarse bread and raw fruits were able to outperform and outlast their American counterparts who ate more liberal fare. Graham also tells about native tribes living on remote Pacific Islands who lived long and healthy lives subsisting largely on coconuts and on wild fruits indigenous to the area. Biblical records also show that peoples in the early days of history often lived for many centuries on their very restricted fare. We know that most of the peoples living in and around the Mediterranean Sea ate largely of fresh fruits and nuts and we find even today that the people living in that area still eat and enjoy much more fruit than the average American does. We well remember another visit to Italy when we travelled on a train going into Rome. It was Christmas time and we were fortunate to share a compartment crowded with six Italian soldiers, just in their teens, who were going home for the holidays. They carried a variety of fruits in their packs and happily shared it with "the old ones," as they called us. Unhappily, as the years have passed, so have many of the fruit stands that formerly graced the back streets of Europe, these having been replaced in many instances by American-type supermarkets.

We think sadly of the little children growing up today in Europe and elsewhere remembering fondly a time some years ago when we spent a memorable and happy day with some 300 beautiful rosy-cheeked children from the countryside outside of Paris, marveling at their good looks and good manners and most of all their composed behavior. We contrast the memory of that day with what we observe in today's American children, many of whom are but hyperkinetic-charged caricatures of what truly healthy children can and should be. Today's sick children are largely the product of culinary "art," the art of making hot-dogs, potato and corn chips, pretzels and "Big Macs" oozing in mustard and relish, of doughnuts and carbonated chemicalized drinks, of sugar-laden cereals that pop and make noises but offer little in the way of nourishment to growing bodies.

We look at our athletes today and see how the various sports are dominated by certain ethnic groups who, because they are not far enough removed from their native, more health-promoting, eating habits, retain a far greater measure of strength, endurance and agility than their Caucasian counterparts who are the products of many generations of gormandizing and a century or more of relative affluence. The peoples of the world cook their fancy dishes and civilizations fall apart while the peoples writhe in the agony of the catastrophic diseases that afflict them.

The dedicated Life Scientist knows that all cooking is folly because it has been shown to be destructive of health. He knows that by its very nature cooking is destructive of the forces that sustain life, that it produces certain adverse chemical changes in the food itself which renders it less capable of perfect digestion and assimilation at the cellular level; that instead of leading one into a world of "hidden delights," the practice of eating a preponderance of food spiced and cooked to "perfection" can, on the contrary, create a subtle erosion of wellness which will be ongoing while life continues and the practice persists; that it can result in tissue and organ degenerative changes upsetting homeostasis; that eating primarily of cooked food can bring upon us the curses of premature aging, disease and death.

## **2.2 What is Food?**

Food consists of those substances which are useful in building the body (as in growth), in the healing and reparative processes which sustain life, and finally, as a source of sufficient energy for the performance of metabolic purposes, and for fuel to maintain body temperature. Seven million new blood cells must be produced every second we live. The material from which these must be manufactured is food.

Food comes to humankind from and is supplied by the vegetable kingdom. Plants and animals live their allotted time on earth and are then, in due course, returned once again to the earth from whence they came. Here they are set upon by the Saprophytes, members of the "in-between" group of living things which do not seem to fit well into either category, especially by members of the Monera Family, the bacteria and molds, who by their own simple metabolic processes disorganize the highly complex organic molecules into simpler inorganic wastes which are excreted back into the soil, there to be taken up as food by the plant and reorganized into widely diverse forms of vegetable matter which we recognize as different varieties and parts of vegetables, fruits, nuts and seeds, these being digestible to some extent by all animals, including man. The original inorganic elements as returned to the soil would poison man but, combined in certain new complex organic formulations and presented to us in food packages especially designed for us, they provide us with rich nutriment for the sustaining of life.

Not all plant products are acceptable but Man is biologically and physiologically structured to accept a wide variety of suitable plant products as his food and, if he sustains himself only with the kinds of food to which he is best adapted, he can maintain his health and experience no disease throughout his entire lifetime provided, of course, that he also provides himself with a suitable amount of all the other known requisites of his organic existence: warmth and sunshine, fresh air, pure water and a congenial (friendly, not hostile) environment, and avoids accidental injury.

Anthelme Brillat-Savarin, the 19th century gastronome, said "Tell me what you eat; I will tell you what you are." Have you eaten too often and too well of sugared goodies? Have you overindulged in animal proteins even though cooked to perfection? If so, there are revealing signs to disclose your secrets. The well-trained and experienced hygienic practitioner doesn't even have to inquire of you as to your past eating practices and preferred foods. He can make a valid judgment of your past indulgences both as to lifestyle and food practices by a combination of careful visual examination and psychologically directed conversational give and take.

Man cannot eat of the soil and live. He cannot take into his system inorganic elements and build a healthy body. He cannot eat the products of decay and have a long and healthy life. He cannot eat of "foods" to which he is not well adapted, such as animal flesh and products derived from or yielded up by animal bodies, and have a long and healthy life. He must, on the contrary, eat foods designed specifically to answer his structural and functional requirements and to eat them without alteration of any kind, largely and primarily in fact as they are yielded up to him by field and orchard. This is food fit for peasant and for king, for child and for adult. Cooking food alters it, the application of heat makes all foods less acceptable, if not repugnant, to the digestive mechanisms provided. Such food is damaged, changed and man cannot fully adapt to it or profit from its use. When he consumes it in response to perversion of his palate, he is required to yield up some measure of his own well-being in exchange for momentary pleasure.

## **2.3 Cooking Processes**

No sharp distinctions can be given to distinguish among the various cooking processes. They all involve heat, of course, and differ only in the degree of temperature applied and the method of applying the heat. The various methods can be categorized as follows:

1. The application of dry heat as in baking and roasting.
2. The maintenance of a constant wet heat as in boiling, simmering, steaming and poaching.
3. Braising or cooking at high temperatures in fat to retain flavor and juices, a method commonly used to sear meat which is then cooked, usually covered, in a pot with a small amount of liquid added, usually water, wine or beer.
4. Frying is used to indicate cooking in fat in a pan or on a griddle over direct heat. Sauteeing is a variation of this method as is deep frying in which the food is totally immersed in the hot fat as is done in the preparation of french-fried potatoes.
5. Broiling or grilling is a method by means of which the foods are exposed directly to heat either in

a broiler or over hot coals, as in barbecuing.

Microwave cooking has recently been introduced and has become exceedingly popular among women who work. Its long-term effects have yet to be evaluated. Slow cookers have also become popular in recent years among women who work all day and like to prepare one-dish meals. These devices cook foods at temperatures of about 200 degrees Fahrenheit and maintain them at these temperatures for eight hours or longer.

Food scientists have replaced many long familiar foods such as fresh orange and other fruit juices with chemical substitutes which compare favorably in taste but not in nutritive value with nature's product. These chemical products have become popular because of their lower price tags and availability requiring little, if any, preparation.

Industry has learned to fabricate many substances now offered to the public as substitutes for the real thing, such products as synthetic chocolate, calorie-controlled foods with low cholesterol and low saturated-fat content for the overweight, substitute eggs and substitute meats, made from textured vegetable proteins, and numerous other pseudo foods. It is projected that in tomorrow's world, the produce section of the supermarket will be hidden away in a corner, difficult to find, if it exists at all. This is why it is important for Life Scientists who value their own health and wish to keep the race viable, to become aware of today's real world and of what will be offered tomorrow, to learn what happens to food when subjected to man-instigated changes wrought by the application of heat, and to make their voices heard. We must learn to relate our knowledge of physiological reality both in the world of commerce and in the halls of government.

## **2.4 Cooking and Vitamins**

Some vitamins are more resistant to high temperatures than others. However, the formulation, development, growth and vigor of an individual are dependent upon whether or not all of his basic organic requisites for living are met and the degree of perfection in all areas will be in a precise relationship to the extent to which each is provided.

Vitamins are one of these basic requirements for living. They are provided for him in man's food and, for man to live in a prime state of health, his needs in this respect must be amply supplied, according to his need. Without a sufficiency of all vitamins, body synergism may be put off balance with the result that growth, development and vigor will be diminished to some extent and, when such sufficiency is long continued, certain deficiency diseases may arise.

The following possible deficiency conditions may be observed:

A. When Vitamin A is deficient:

1. A failure of the bony structures to grow normally.
2. Excessive dryness of the outer and inner skins.
3. A lack of adequate mucous membrane secretions.
4. Various eye diseases.

B. When Vitamin D is lacking:

1. Abnormal bone and teeth formation.
  - a. Rickets with malformed legs, spine, etc.

C. When Vitamin E is in short supply:

1. Changes in blood making.
2. Adverse changes in the musculature and in the circulatory and central nervous systems tissues.
3. Increased loss of Vitamin A and Carotene by oxidation in the intestines.
4. Red blood cells become more susceptible to destruction.

D. Vitamin B Complex - Specific members may give rise specific deficiency diseases, among which we find:

1. Reduction in general metabolic efficiency.
2. Nervous disorders.
3. Loss of appetite.
4. Certain gastric disorders.
5. Skin lesions (outer and inner skins).
6. Energy transmission failures.
7. Insomnia.
8. Muscle pains and cramps.

As Life Scientists we must be aware of the fact that all diseases are the product of toxemia. An insufficiency of vitamins can be a contributing factor, not the sole cause, of a diseased state. The root causes of any diseased state are, multitudinous, not capable of isolation.

When man first began to use fire on his foods, he began to destroy himself. One reason why this is so is because the application of heat is somewhat destructive of vitamins and the higher the temperature, the more destructive heat will be to the vitamin presence. As we indicated previously in our discussion in Lesson 39, vitamins are intimately interwoven with all the other nutritional and chemical elements offered in food and that the effectiveness of all nutrients can be somewhat reduced and even perhaps disintegrated by a deficiency in any one nutrient and this, of course, would include vitamins.

A few specific examples of how heat can reduce vitamins in certain foods will suffice to show how destructive normal cooking can be to one vitamin, Vitamin C. Measurements are given in milligrams and are derived from data supplied by the U.S. Department of Agriculture.

Apricots, fresh halves. 1 cup	16
Apricots, canned, water pack, 1 cup	10

Mung Bean Sprouts, raw. 1 cup	20
Mung Bean Sprouts, cooked. 1 cup	9

Blackberries, fresh. 1 Cup.	30
Blackberries, canned, water pack, 1 cup.	17

Pears, 1 cup fresh, sliced or cubed.	7
Pears, canned, water pack. 1 cup.	2

From these few examples, the student can see that, while the Vitamin C presence is not completely destroyed, it is reduced. Any reduction, of course, will change the proportions planned by nature and will, therefore, be anti-health.

When foods are examined for specific content, we find that all foods contain essentially fiber, vitamins, minerals, enzymes, carbohydrates, fats, proteins, some flavor enhancers, water and poisons of one kind or another, and in varying amounts, even in man's most desirable foods, these being easily eliminated by

the normal excretory processes. Food, however, is far more than the sum of its divided and carefully separated parts. Why this is so, no man knows but it is a proven and indisputable fact that man will starve and die if fed solely on any or, indeed, on all of these isolated food factors, but will thrive when he eats unfragmented nature's food packages that contain the very same substances.

Persons who eat preponderantly of cooked food consistently deprive themselves of vitamins which, as we recall from our previous discussion in Lesson 39, are the important metabolic regulatory assistants to hormonal function and the vital enzymatic catalytic action. We view with sadness the meals eaten by many of our elderly citizens who frequent cafeterias and similar moderately priced restaurants.

Invariably their trays reveal depleted, cooked, poorly-combined foods. The usual menu consists of a meat dish, one or two cooked vegetables, usually only one, rolls made of devitalized white bread plus a dessert, frequently a piece of pie or cake. Many can afford but one or two items and, more often than not, choose a meat dish, adding perhaps a roll. Few even do more than glance at the array of salads and fruits. Certainly, the vitamin presence in such meals must be greatly diminished, if not completely so. It is little wonder that their gray complexions and their curved spines reflect the weariness within, of both body, spirit and soul, these being the visible signs of malnutrition and systemic decay.

Most American children today are brought up on cooked, vitamin-deficient foods. It is time that we hygienists take a critical look at America's children and observe their curved spines that encapsulate and crowd the lungs and place all abdominal organs in a stressed posture. Take a look at all the mouth-breathers among them. Their nasal and respiratory passages are blocked with mucous discharge. We see them in school classrooms where we sometimes lecture, teenagers slouched over their desks, their bodies reflecting systemic fatigue; or, the opposite, bodies with taut nerves, falsely stimulated. Far too many of them are hyperkinetic sugar-starch-fat-rich young adults with still-growing bodies trying to make it on vitamin-deprived cooked foods. Unfortunately, it is our belief that most of these teenagers will live to curse the world of which they are a part.

So long as malnourished persons eat of cooked devitalized foods, they can take all the synthetic vitamins in the world and still not meet the needs of their bodies for these nutrients. The only sane way to satisfy our requirements for vitamins is to eat the foods that supply them: fresh ripe fruits and vegetables. There can be no piece-meal approach to dietary adequacy and superb health. Optimum nutrition is essential and it can be obtained only when the food eaten is optimum in all nutrient values including vitamins.

These required food values will be optimum only in freshly-picked, organically-grown, ripe fruits and vegetables and these eaten uncooked and as soon after picking as possible since some vitamins are reduced in value upon standing, even when refrigerated. Freshly-picked foods such as we have described will be whole foods, rich not with isolated food factors of doubtful value, but rather with all of them, properly proportioned as designed by nature's wonderful food factories, the living plants.

Fresh uncooked foods will supply the body with a superabundance of all the food factors we require and with all the vitamins, known and unknown. Cooked foods will always offer an inferior depleted product, one destructive of health.

Vitamin A is regarded as being stable to heat at ordinary cooking temperatures but both the vitamin and beta-carotene are oxidized and destroyed by air. Therefore, when food is cut and chopped and then cooked in water and the water discarded after cooking, considerable amounts of this vitamin will be lost when foods are cooked in this manner.

The vitamin D content of most foods is either nonexistent or present only in very small amounts. Therefore, cooking is not an issue in the case of vitamin D. At any rate, our requirements for vitamin D can be fully met when we expose our bodies to sufficient sunlight.

Vitamin E is somewhat affected by cooking. However, it is very sensitive to slight oxidative changes in the fats contained in the foods in which it is found. Therefore, cooking will produce certain destructive chemical modifications in this vitamin by disorganization of the fats.

All members of the vitamin B complex are water-soluble and, consequently, cooking foods rich in members of this group can be highly destructive of the entire complex. High temperatures dry heating is somewhat less destructive but will also destroy to some extent B complex member vitamins.

The extent of vitamin loss by cooking will depend upon the following variables:

1. The method of cooking employed as, for example, boiling, stir-frying, as in wok cookery; and so forth.
2. The temperature to which the food is subjected as, for example, cooking at lower temperatures as compared to roasting and baking at high temperatures.
3. How long the food is subjected to the heat.
4. The relative presence of oxygen, as for example, heating food in a covered pot will reduce vitamin loss as compared to cooking without the lid on.
5. The pressure to which the food may be subjected. Cooking in an ordinary cooking utensil will not produce as much vitamin loss as will be occasioned when food is cooked in a pressure cooker which not only builds up the pressure but also maintains the cooking temperature in excess of 270 degrees Fahrenheit.
6. The presence or absence of light. Darkness tends to protect against some measure of vitamin loss.
7. How much and to what extent the food has been diced, shredded and/or chopped before cooking.
8. The material from which the cooking utensil is made, iron being probably the most destructive to vitamins. Iron utensils are highly porous and whatever food is cooked in it loses a certain portion of its vitamin content to the pan. Greases, juices and blood from meats soak into and remain in the porous iron, carrying with them any remaining vitamins that these vitamin-poor foods may contain.

Herbert M. Shelton points out that the average loss of vitamin C in foods served to patrons of restaurants is 45 percent; of thiamine, 35 percent. It is wise for persons who must eat in restaurants to eat early, just after the food is placed out in expectation of the early supper crowd, about four o'clock in most areas. The newly-prepared food would be at its best at this time. We also advise patrons to patronize those restaurants where salad bars are featured.

We have no trouble eating while travelling. If we fly, we either do not eat at all or we advise the air carrier the day before take off that we wish to be served a fruit meal. There is no extra charge for this service. If we drive, we carry an assortment of compatible fresh fruits with us. If we stay in a town or city for several days, we occasionally eat at a restaurant like Big Boy which features either a fruit plate that is quite acceptable or a well-equipped salad bar. Many of the better steak houses pride themselves on the variety of salads featured. We avoid most cafeterias because their salads are usually covered with sugar-salt-vinegar dressings or liberally dosed with commercial mayonnaise.

## **2.5 Cooking and Food Fibers**

The chemical composition of all fibers found in vegetables is predominantly cellulose, a very complex polysaccharide. So complex is the cellulose molecules that it is largely unaffected by the application of alkaline secretions, a fact which in and of itself means that cellulose fibers cannot be fully digested by the ordinary digestive secretions produced in the human digestive canal.

The student will recall from his previous studies that all carbohydrates are composed of carbon, hydrogen and oxygen in varying arrangements, these being divided into several categories: simple sugars, complex sugars, gums and pectins, dextrans, starches, glycogen and cellulose. The formulas for each category may be written as:  $C_m(H_3O)_n$ .

The number of carbon atoms and the number of possible combinations of  $H_3O$  vary according to the complexity of the various molecules under consideration, the more complex carbohydrates being formulated of many simple sugar molecules (single molecules) all joined together, somewhat like freight

cars in a train.

Glucose, a single comparatively simple molecule, is the monomer unit from which two major families of carbohydrates are formed: the starches and celluloses. Both of these two complex formulations are hydrolyzed (that is, disorganized) by a solution of certain acids in water to form smaller chemical units and eventually, when fully resolved, into chemical "fragments" called glucose.

The starches can be hydrolyzed by enzymes found in the human saliva, but the celluloses found in fiber cannot. According to Davenport (Physiology of the Digestive Tract, 3rd Ed. by Horace W. Davenport, Yearbook Medical Publishers, Inc., 35 East Wacker Dr., Chicago, III.), no members of the mammalian family possess an enzyme to catalyze the resolution of cellulose. In man there is a form linkage between an enzyme such as ptyalin and the starch, the two "fitting" together, as it were. This fitting together is called "alpha-glycoside linkage." Such is not the case with the celluloses. The enzymes in saliva and elsewhere in man's digestive tract do not "fit" into the cellulose molecular arrangement and therefore have no effect upon the celluloses. This nonfitting linkage is known as a "beta" linkage. This is why the fibers in uncooked food can pass on through the digestive tract virtually unchanged chemically. Cellulose is partially digested by bacteria in the colon with the formation of volatile fatty acids which can stimulate peristalsis and act as an aid to defecation. Most of the cellulose contained in foods eaten will be given off in the feces when defecation occurs at least once in 24 hours but in constipated persons such will not be the case. Davenport states that in constipated persons digestion occurs within the central part of the fecal mass, and acid products may be absorbed (p.212).

The three classes of carbohydrates, according to molecular complexity, are:

1. Monosaccharides - one molecule (the monomer unit)
2. Disaccharides - two molecules joined together
3. Polysaccharides - more than two molecules.

Cellulose is a polysaccharide and the most complex of all the carbohydrate molecules. The polysaccharides have very large molecules: about 10 molecules being joined together to form glycogen, 25 for the simpler starches and 100 to 200 for the celluloses.

For efficient and thorough digestion the body, requires bulk in its food and nature has skillfully designed food for man which contains appropriate amounts of bulky cellulose fiber, the amount incorporated in man's food apparently being proportioned exactly according to the design of the human alimentary canal and its ability to make use of it. Thus, it can be seen that persons who eat food not intended as food for man will do the body a disservice as will those persons who may eat suitable food but then alter by application of heat, the fiber content of that food, as in canned cooked food for babies.

We might assume from our discussion thus far that some foods might contain too much fiber, more than the human body might be able to handle efficiently. This is indeed true and such foods should certainly be either completely avoided or, at least, restricted in the human food intake. They place too great a burden on the peristaltic and eliminative capabilities of the intestinal equipment. The cellulose in some foods, especially if consumed uncooked, can be abrasive to the mucosal lining and, long term, could lead to irritation and inflammation of the food canal. We refer to such foods as most roots, dried legumes and grains. In the uncooked state, these foods can be highly irritating as well as obstructive to free passage of the fecal residue, a condition which leads to packing of the canal with accumulating amounts of dried obstructive fiber, making the walls more or less rigid (the "piped" colon) and laying the groundwork for putrefaction and fermentation of contents. Obviously, too, the high cellulose content of the mentioned foods prevents complete digestion and interferes with absorption of nutrients that may be present in the foods.

We note that the fiber content of the foods generally conceded as being most acceptable to man's digestive capabilities is quite low as, for example, in fruits, the perfect human food. Even so, persons who subsist largely on uncooked fresh ripe fruit do not suffer from constipation but, to the contrary, have regular and sufficient fecal exodus. When the foods that are best adapted to man's requirements are

eaten, the fruits, the leafy green vegetables and perhaps a few nuts and edible seeds, and these are well masticated, we note that the digestive process extracts a maximum quantity of nutrients from the food and leaves most of the cellulose behind intact and this is then readily eliminated.

The ingestion of any unwholesome food, whether it is cooked, processed, or improperly combined will eventually result in systemic toxemia. This unwelcome state of ill health affects the entire organism since the body reacts and functions as a whole.

The body may be thought of as a unified structure working in harmony to maintain health. All bodily functions will be affected by the toxemic state and this includes the large intestine. Thus, constipation is a common result which we bring upon ourselves by eating cooked or otherwise denatured foods.

However, when raw fruits and vegetables are eaten in the presence of true hunger, all bodily functions will proceed unhampered and the digestive process also proceeds perfectly.

Dr. Vetrano cautions us to follow our instincts and eat only when true hunger is present for proper digestion of our food. She says, "When you are truly hungry the exact quality and quantity of salivary and gastric enzymes are secreted for the amount and kind of food eaten and the body moves the food along the gastrointestinal tract fast enough for proper digestion yet slow enough for maximum absorption."

We must not think of one particular food to move our bowels or another food to improve our vision, etc. The proper food will provide the correct conditions for the human body to carry on *all* of its functions and health will be the natural result. When the entire organism is healthy, so will be the bowels and the body will eliminate all of the waste products of metabolism along with the food fiber.

We had a client not too long ago whose lower GI X rays were remarkable. She had a piped ascending colon that was fully three inches across, the transverse colon had fallen and was U-shaped. It, too, looked stuffed with debris while the descending colon was twisted, gross-looking. Her dietetic history revealed that she ate the usual cooked American fare. Undoubtedly, the silent nerve pain channels had been well etched over many years. Just over 40 years of age, she now sees the evidence of 40 years of intestinal mismanagement, of eating so much cooked food and most of it of questionable quality. It will take considerable time to undo the damage, if it is even possible. However, there is some evidence of improvement. She had been unable to have normal bowel movements for over 12 years and is rejoicing in the fact that she is now able to have a normal, unassisted bowel movement once or twice a week. Occasional short fasts to permit rest and healing of her abused body followed by the gradual introduction of more and more uncooked foods, especially watermelon, plus a few leafy vegetables and a very small allotment of nuts three times a week have been instrumental in her progress. Her progress might have been more rapid except for the fact that this client had a tendency (as many do) to regress and, at such times, her commonsense and new knowledge fell victim to habit and she would indulge in the old ways. Fortunately, as time went on, the periods of regression became fewer although even yet they occasionally reassert themselves. We are confident that the day will come when she will have much improved digestive and eliminative powers although it is doubtful that she will experience full recovery since her colon and other organs have been extensively damaged both structurally and functionally, although we must emphasize that we should never shortchange nature. She can often surprise even the most experienced practitioner!

If we are presently not eating an all raw food diet, it would seem, from this discussion, the better procedure to change as quickly as possible to this more healthful way of eating. The body will then respond favorably and total well-being will be the result.

Every food intended for man has its required proportion of largely indigestible cellulose fiber. It is important that we consume our food in its natural state and not cooked, juiced or blended. Dr. Vetrano explains that, "If the food is whole—unjuiced, unblended and uncooked—like wild animals take their food, it will occasion the flow of more digestive juices than if the food has been separated from its fiber content or if the fiber has been excessively macerated. When the natural fiber touches the walls of the

stomach, it occasions much more gastric secretion than were it in the form of juice or in the form of a blend."

Dr. Vetrano further states that such practices as cooking, blending or juicing affects the fiber content which is necessary for the proper movement of food through the digestive canal and for the stimulation of the secretion of normal digestive enzymes.

However, we must keep in mind that it is not the fiber alone which ensures health of the digestive canal. It is a proper diet combined with all of the other aspects of a Hygienic lifestyle which will result in health of the entire body and all of its functions, including digestion. By following all of the principles of Life Science, the body will be free from toxic overloads which result in constipation and other disorders.

## 2.6 Cooking and the Minerals

There are many factors that alter and destroy the mineral presence in foods. One of the most destructive of the various processes which precede the actual cooking process itself is the paring and cutting of foods. In many foods, especially the fruits, the greatest concentration of minerals is found in the skin or peel and these are often totally discarded when foods are peeled as, for example, apples or the tuber, the potato. Some foods have high concentrations of minerals stored directly *under* the skin and these, too, are often removed in peeling. There are foods, of course, which must be peeled before eating, such as the banana and many citrus fruits. All nuts require shelling. However, in considering the foods best adapted to man, by far the greatest number can be consumed whole and require no peeling whatsoever.

The cutting, shredding, chopping, etc., of foods prior to cooking exposes a larger surface to mineral loss and, if foods must be cooked for one reason or another (for example, in very debilitated cases), then it would appear best to cook as many foods as possible whole in order to minimize such loss.

Boiling is the poorest method of all. it is highly destructive of minerals. One can illustrate this fact very easily. Place some carrots or other deep yellow or deep green vegetable in a pan. Add water to cover and bring to a boil. Boil for two or three minutes and then decant the liquid. The water will appear colored, either yellow or green, indicating that many nutrients including the minerals have been dissolved in the liquid and are no longer contained in the food being cooked. The mineral loss will, of course, be greater when the foods have been cut prior to placing them in the water for cooking. According to the *Journal of Home Economics*, Vol. 17, No. 5, the average loss by boiling in foods is:

Iron	48%
Calcium	31.9%
Phosphorus	46.4%
Magnesium	44.7%
From the potato, total loss	50%
From the cabbage, total loss	40%
From the Carrot, total loss	30%
From the apple, lost by peeling, boiling and	50%

## 2.7 Demineralization Processes

Dr. Shelton tells us that mineral loss from foods by cooking is accomplished by the following means:

1. By Leaching: the minerals are carried out in the food's own juices which then run out into the surrounding liquid.
2. By Volatilization or Evaporation: Certain minerals, iodine and sulphur being prime examples, will "bubble out" from certain foods upon the application of heat. In the process of pasteurization of milk, the loss of iodine can amount to as much as twenty percent. Any time a person can smell cooking odors, he knows that nutrients are being lost.
3. Chemical Alteration: Certain mineral salts contained in foods are changed chemically by the application of heat, so much so, in fact, that they become biologically unavailable to the body. Pasteurization of milk, for example, changes the calcium in milk from its organic form to an inorganic molecule which is completely useless to the human economy.. In the green leaves of plants, in fresh ripe fruits, in the edible nuts and seeds are found all the minerals deemed necessary to preserve health and to extend life in health. It must be understood, however, their usefulness does not depend solely on the presence of a sufficient quantity and variety of minerals alone, even though all, other nutrients are also present; but, largely upon the proportion of all these vital nutrients to one another and, most particularly to the presence of the organic mineral molecules and to the ratio between the acid carrier elements and the alkaline mineral elements. We refer, of course, to the acid-alkaline balance. With the unavoidable mineral loss that ensues whenever food is cooked, the possibility exists that this balance can be disturbed so much that an acid-alkaline imbalance will result (acidosis or toxicosis).

## 2.8 The Mineral Presence

Mineral elements comprise less than five percent of our body and only about one percent of the weight of cellular protoplasm. However, minerals are essential to all metabolic activities. Their presence is required to sustain the alkalinity of body fluids; they are required for structure, in healing and for repair.

Our body requires a great variety of minerals, some more, some less. Some of the more common elements like carbon and hydrogen are plentifully supplied by fruits and vegetables; others like potassium, sodium, magnesium, and other alkaline mineral elements required to maintain fluid alkalinity and salinity are found liberally in fresh leafy green vegetables. In our view, these latter foods should comprise an important part of the dietary intake. The important micro-elements, the so-called trace minerals, including iodine, chromium, zinc, molybdenum, manganese, copper, vanadium, fluorine, selenium, and so on, are also required but in unknown amounts. These trace elements are required to feed the body's cellular factory production line and to participate in the thousands of actions and reactions that are going on. We require a full assortment of all required minerals to keep us breathing, growing, regenerating, healing; to keep us alive. The dynamic importance of minerals to health is not always appreciated and probably few among us receive our full quota of minerals nor do we receive the ones we get in their original proportionate distribution simply because most people eat largely of cooked food.

Many sick people improve dramatically when they change from the ordinary mixed diet to the vegetarian fare, even though cooked, but when they change to an all raw food intake, they are often amazed at the dramatic results obtained by them within a very short time. It is not only important to know where the food you eat originates but it is even more important to eat that food unfired, replete with all its minerals in their correct proportionate arrangements and combinations prepared expressly for human physiological machinery in nature's grand plant factories.

Mineral deficiencies and imbalances produced by poor food selection and by cooking can lead to many disorders: to general malnutrition, increased sterility, development of homosexual tendencies, body encumbrances of many kinds, concretions, skin moles, blemishes, general debility and weakness, as well as to other diseased conditions.

## **2.9 Fragmented Foods**

Fragmented foods are foods in which certain nutrients are in short supply. To ensure superb health throughout a lifetime, food must contain all the nutrients required for the living process and these elements must be furnished in organic combinations and in certain prescribed arrangements as they have been formulated in natural foods. Life cannot be maintained for long on fragmented foods. Cooking fragments food because, among other things, it disrupts the mineral presence, throwing it out of balance.

Organized by nature, iron, phosphorus, potassium, magnesium, sodium, potassium and all the other minerals contained within the highly organized molecules of foods can be digested, absorbed, transported and assimilated with highly beneficial results. Cooked, fragmented, demineralized or mineral-poor foods create problems for the digestive process, problems which lead to imperfect processing all along the nutritive chain. A life sustained on cooked mineral-poor food will be plagued from time to time by both minor and chronic diseases; such a life will experience varying amounts of weariness, fatigue, a lack of endurance and strength and will be shortened commensurately with the existing mineral deficit.

A diet rich in its mineral content, unfragmented by cooking, on the other hand, means smaller quantities of food must be eaten, fewer waste products with quicker elimination, improved endurance, greater strength, the maintenance of a proper blood viscosity and alkalinity, clean fluid channels, together with excellent general health, both physical and mental.

As Life Scientists we must understand that no proximate food factor alone is capable of sustaining vital force and further than this, that fragmented foods, even though they may contain many or even most of the required nutrients, are also incapable of sustaining life without creating deficiencies which, in the final analysis, are destructive of some measure of health. When we choose mineral-rich foods and then eat them uncooked, masticating the foods well, we then will provide our body with the best raw materials to produce healthy cells and tissues. We can eat twice the quantity of cooked fragmented food and yet not obtain an equivalent amount of biologically available mineral wealth nor can we be sure to obtain our full requirement thereof.

## **2.10 Cooking and Enzymes**

Perhaps the greatest argument against the practice of cooking lies in the fact that heating any food above approximately 122 degrees Fahrenheit destroys the food enzymes. Water boils at 212° so we can readily see that even the application of comparatively low heat can destroy the enzymes.

Enzymes present in fruits and vegetables play a vital role in the metabolic activity of the plant cells. They are complex proteins formulated in and by the plant cells from primary inorganic elements soluble in water and taken up by the roots of the plants and by the combined action of sun and air they become incorporated into the cellular plant community.

Like all other proteins contained in foods, the chemical structure of the complex enzyme molecules is changed by the application of heat and the catalytic force destroyed. Cooking will kill food enzymes just as effectively as an excessively high body temperature will cause us to burn up. Heating food effectively stops the vegetable metabolic action. In other words, when heat is applied to a plant in excess of 122°, the life force of the plant comes to an abrupt end.

When raw food is eaten, the food enzymes remain intact. Just like the protein in the food, the enzymes are digested in the stomach and become a part of the nutritive package offered up by the particular food,

fruit or vegetable, nut or seed. Humans have the ability to manufacture their own cellular enzymes from the nutrients transported to the cells in the fluids of the body. Thus, if we supply ourselves with adequate amounts of suitable kinds of raw foods we will more easily and thoroughly digest our food, we will absorb a goodly quantity of nutrients to supply cellular needs and we can then formulate the required human enzymes, as the need arises.

However, when we eat cooked food we then fail to supply the wherewithal to manufacture our own enzymes and, if we remember that enzymes activate and control all the chemical actions and reactions within the cells and regulate the energy output for all physical and mental activity, we can see just how important the enzyme presence is to the continuance of life.

Adjustment by the body to the eating of cooked enzyme-poor food is always done at the expense of vitality, endurance and strength. However, many persons are afraid they will lose much weight on an all raw diet. This is generally true, but only in the early stages as the impurities in the blood and cells leave. After the housecleaning has been well taken care of, the lost weight is usually regained in short order. John Richter, author of *Nature—The Healer*, found this to be true. In fact, like most people, he first lost considerable weight and then regained all he had lost plus a few additional pounds. In the process, he regained his health, reporting in at 84 years of age to be totally without aches and pains of any kind.

Earlier in this century a wrestler, by the name of George Hackenschmidt known as the Russian Lion, toured the world competing with all the great iron men of the day. He successfully threw all who dared to test his strength and skill. According to Dr. George R. Clements, his diet consisted of the following:

Breakfast: lettuce and 5 or 6 Brazil nuts.

Second Meal: fresh raw fruits

Third Meal: fresh uncooked vegetables.

Dr. Robert, who eats only very occasionally of any cooked food, went from 212 pounds down to about 108 pounds and then began to add on weight until he reached about 128 pounds, where he has remained now for many years. We might point out that the new flesh gained is good firm, much-healthier flesh, and the weight obtained will be in keeping with body structure. On a hygienic regimen complete in all particulars, including a totally raw food intake, both the obese and the underweight tend to return to a healthy weight, normal for them.

Enzymes are the life principle and when they are lacking, their absence will soon be felt. When our food is vital, our bodies respond and we also become more vital. The destruction of enzymes by the application of heat may result in toxicosis and digestion is thus delayed or incomplete. In any event, we have long known that animals fed solely on a diet consisting of cooked food soon sicken and die while those fed their natural food and uncooked, thrive generation after generation. It may be well that the unique talent of enzymes to catalyze chemical reactions at low temperatures serves to conserve body energy and time not only in the cells but also in the digestive tract itself. Certainly the enzymes servicing the alimentary canal act in this capacity.

## **2.11 Cooking and Proteins**

Every step taken to prepare foods for cooking and also the actual cooking process itself produces changes in the nutritive value of the food. Protein content and value is no exception for it, too, is affected profoundly by the application of heat.

As the student has already learned, the protein molecules are very complex, so complex that they are known as "macromolecules." When these macromolecules are subjected to heat, they are chemically changed, becoming less digestible in most instances. Egg white is an exception. The albumin in egg white is indigestible raw and quite indigestible when completely hardened as in hard boiled eggs. However, when slightly curdled as in poached and very softly boiled eggs, the egg white is most digestible.

Meat protein undergoes important changes beginning at about 147 degrees in some instances as with fish, for example. If one is frying fish, one can observe a "leakage" of fluid begin at just about that temperature and, by the time a temperature of 151 degrees Fahrenheit has been reached, the pan will evidence considerable fluid in it and the texture of the fish will have changed having become quite dry and also less digestible, the protein having been coagulated and rendered less soluble, the water having been removed by the increased temperatures.

Beef and lamb are more easily digested raw than when cooked.

With these two meats the protein starts to harden at temperatures above about 150 degrees and at 160 degrees has been hardened. One time we were the only passengers on board a Dutch freighter which we had boarded in the harbor at Marseilles for a trip across the Atlantic where we were to study eating habits among the island people in the Caribbean. We ate with the captain and officers and observed that the meats served were cooked only to a depth of about one-quarter inch with the rest of the meat, usually beef, oozing blood. Many cultures in Europe we found eat lightly of meat, serving it mainly in very small portions and well cooked, as in various stews, but the Dutch, apparently like their meat in large quantities and almost uncooked. The only meats we observed being well cooked on that voyage were bacon and sausage.

If one examines a typical protein molecule as might be found in animal protein, one can observe various NH<sub>3</sub> groupings, the N indicating nitrogen, the H, hydrogen. These are known as amines. In cooking and especially in the presence of water, these amines are replaced by an hydroxyl grouping, that is by an OH group, the O being the symbol for oxygen. These OH groupings cannot again be replaced by NH<sub>3</sub> by any mechanisms present in the human body. This is why the cooked protein becomes useless. In some methods of cooking, it is believed that certain amine groups are actually split off even though no water is used in the cooking.

Certain proteins contain sulphur in their molecules. In the presence of water, this sulphur can also be split off. Cystine, an important amino acid which contains some 27 percent sulphur, is a typical example. Sulphur is found in all members of the cabbage family and it plays an important role in the human body as a disinfecting agent. The student will observe that in cooking members of the cabbage family, one can often be aware of the smell of sulphur as gases leave the cooking utensil. What is left is an inorganic molecule made up of inorganic atoms, which are useless to the economy. Cystine is an important element in the formation of red blood corpuscles but not a desulphurized changed cystine, but the whole organic molecule.

The vital factors, the complete amino acids, are destroyed and rendered useless as food factors to the precise extent that they are destroyed by the heating process. Methionine, another important sulphur-containing amino acid, is similarly affected by cooking. This amino acid is an important constituent of the body serum, of hemoglobin and of tissues. We can see how cooking such methionine-containing foods as Brussels sprouts, cabbage, cauliflower, kale, pineapple, apples and Brazil nuts could render their constructive values almost useless.

Similar modifications in structure occur with all the amino acids in cooked proteins, essential and nonessential. When we consider the vast complexity of these molecules, we can appreciate perhaps more fully the value of retaining the original organic structure. It is difficult, if not impossible, for the human body to build its own protein if it must first untangle an inorganic mess even before it starts.

Ragnar Berg, the Swedish scientist, reported long ago on research that showed that boiling meat even for a comparatively short time changed the nature of the phosphate presence in protein. Phosphorus is essential to blood and brain building. And yet, how often are the following valuable foods cooked, valuable because they contain generous amounts of phosphorus in them: kale, asparagus, Brussels sprouts, Savoy cabbage, carrots, cauliflower, cucumbers, lettuce, Brazil nuts, walnuts, huckleberries, blackberries, cherries and black mission figs. Many of these same foods contain iodine which, on heating, is also changed to HI or hydriotic acid causing damage to the thyroxine presence.

It is interesting in this respect to note the recent release by an "expert" panel of the National Academy of Sciences (as reported in the public press on June 17, 1982) in which, for the first time, it is acknowledged that a faulty diet is related to cancer. The panel urged people to increase their consumption of fruits and vegetables and especially of members of the cabbage family, such as broccoli, cauliflower, kale and brussels sprouts which "contain natural cancer-inhibiting substances."

Could these perhaps be the sulphur in the amino acids which are destroyed by the cooking process? Perhaps for the first time this official body has also recognized the importance of an adequate vitamin intake, emphasizing the vitamin C contained in dark-green leafy vegetables and deep yellow fruits and vegetables. As Life Scientists we, of course, know that cancer represents the end-point of a long and involved biological evolution, one made operational by a multitudinous number of physiological insults, a faulty diet being one.

The more the complex molecules of protein are heated, the more changed is the colloid form. The water-containing colloids (called hydrophilic) are converted into water-reduced colloids (hydrophobic). Unfortunately, perhaps, the human liver is designed to accommodate only hydrophilic colloids. After hydrophilic protein colloids are processed by the liver, the waste products can be neutralized very handily by the sodium stored in the liver for just such a purpose and then can be flushed out as sodium salts, carried out of the body via the bile and feces. The kidneys take on the remaining nitrogen wastes which are flushed out in the urine as soluble urea.

Heating proteins, because it alters the protein molecules, makes them more subject to putrefaction in the intestines, a decaying process which, over the years, can lead to grave disorders of many different kinds according to inherited individual strengths and weaknesses and, of course, to the general overall profile of the individual, both as to his eating habits, past and present, and to his lifestyle, past and present. Past indulgences must have left their imprint.

Dr. Kouchakoff discovered that cooked meat causes a tremendous proliferation of white blood cells in the bloodstream, the increase being two to four times the normal. The body produces these white blood cells for a purpose: they surround toxic particles and then escort them to the nearest exit point, usually the kidneys. We note and it is so recognized that leukemia is always associated with an extremely high uric acid reading in the blood.

In all likelihood, other components than protein are also affected and reduced to a lower inorganic state, less useful to the cellular community. We have already noted a few. The experiments performed on cats by F.M. Pottenger, M.D. and D.G. Simonsen at Yale are well known but deserve repeating here to emphasize the harm cooking can do to proteins so essential to growth, building, healing and repair. In these experiments the cats were divided into two groups. The group that received all uncooked food lead normal lives and remained healthy through several generations, in fact until the termination of the experiment. The other group, fed only on cooked food, rapidly failed in health and members of the second and third generations lost all ability to reproduce. The members of this group suffered from diverse diseases including "softening of the bones, paralysis of the legs, thyroid abscesses, convulsions, cyanosis of the liver and kidneys, an enlarged colon, degeneration of the motor nerve ganglion cells throughout the spinal cord and brain stem, with some cells even affected in the cerebellum and cerebral cortex." Do we not observe similar conditions among our friends and neighbors who eat consistently of cooked foods? Certainly, we are observing considerable deviation from normal sex habits among both sexes and among women, especially a departure from biologically normal female instincts (some lessening in devotion to the raising and protection of the young they have brought into the world, and increased lack of desire to bear children, promiscuity, and so on). An increased number of males fail to provide for their offspring. Many of both sexes have become either homosexuals or sterile. While other influences are no doubt causative here we cannot but help believe that the evidence of the cat experiments points an accusing finger at the tendency to emphasize cooked food almost exclusively in our dietary habits. Because of the high temperatures, cooking by boiling, frying and by pressure cooker are particularly destructive of the important amino acid molecules.

It takes many generations to affect conclusive, results— two to four in the cat experiments. The human race has been eating cooked food now for a long time and in increasing amounts. We are no doubt witnessing the evil effects of this practice and are apparently helpless to stem the tide of disease among our peoples. Someone has well remarked that it is the uncooked molecules in the food we eat that maintains life. The only hopeful thing we see at the present time is the growing interest in sports and the interest many of our young people express in the study of nutrition, especially in natural hygiene.

## 2.12 Cooking and Fats

Cooking fat-containing foods renders the fat and the foods less digestible and, in some cases, even highly toxic. Foods fried or cooked in fat and all foods with a high-fat content are more or less difficult to digest depending on the quantity of fat present and the temperature at which it is cooked. The free use of fat, cooked or uncooked, encourages digestive disorders mainly because its digestion must wait until it passes out of the stomach. The fat, when mixed with other foods, has a tendency to form a coating over the other food particles and the digestive juices and enzymes have difficulty penetrating this coating. This difficulty is augmented when the fat has been heated. Additionally, the fat coats the lining of the digestive tract impeding free secretion of digestive juices. But, that is not the end of our difficulty with fat. The fat will form around the individual complex food molecules preventing resolution into smaller elements; in other words getting in the way of the necessary chemical separations. Putrefaction of protein substances and fermentation of carbohydrate molecules are a natural sequence.

Fats, as found normally in nature's food packages, need not be avoided but, even here, one can overindulge as many do, eating too many avocados and snacking on nuts at all hours. It seems that many hygienists are guilty of the last. They do not seem to understand that every time we put anything into the oral cavity, we put the wheels of digestion, absorption, transportation and assimilation into motion, we activate every organ and system in the body and waste our vital reserves by so doing.

The application of heat to fats breaks them down chemically into fatty acids which are nonassimilable and, consequently, these become free-floating poisons in the body fluids. Experiments on animals have shown heated fats to be carcinogenic to the animals. As Life Scientists we know that cancer is an end-point reached after many indiscretions, and is not caused by a single isolated factor. However, we also know that fats (triglycerides) are responsible for body balance of the metabolic processes working with the nervous system. High triglyceride count slows the utilization of minerals causing excess mineral build-up and depression of the nervous system communication capabilities, a state certainly capable of confusing the entire system's operational accuracy.

In September 1976, the Washington Post reported on the dangers of increased fat intake and especially of cooked fat, as shown by the research of an Australian scientist, E. Bruce K. Armstrong of Perth Medical Centre. It was reported that women eating diets rich in fat and especially in animal fats apparently showed an increased risk of developing womb cancer, often localized in the lining of the uterus. This was of great interest in the U.S. since the incidence of this kind of cancer among women was shown in 1975 to be the highest among 23 countries. Our daily fat consumption at that time was fourth, and, as students well know, most of this fat was cooked fat.

Armstrong also cited studies that showed a close correlation among endometrial cancer and breast cancer and colon cancer, both of these last cancers being suspected of having a cause-effect relationship with fat consumption. Armstrong cited studies dating back to 1958 linking obesity to endometrial cancer, but emphasized a 1973 report which suggested that dietary fat displays larger role than sugars and starch in causing this disease.

In a 1975 survey of 23 countries, it was shown that the per person daily consumption of fat was listed at about 150 grams in the U.S., compared with about 40 grams in Japan and Nigeria. The rate of endometrial cancer in women was 34 per 100,000 in the U.S. and only about 5 per 100,000 in these two countries. Certainly these studies seem to support the conclusion that excess fat consumption, and especially cooked fat, may well be one of the causative factors which, added to multitudinous other

physiological insults, can lead to the biological evolution which terminates in cancer.

A number of witnesses before the Senate Select Committee on Human Nutrition and Needs have testified to the epidemiological evidence correlating dietary imbalances to increased cancer incidence and most, if not all, have pointed an accusatory finger at excess fat which is heated fat. We have also observed in this lesson that heating food disturbs and, in some cases, destroys minerals, vitamins and enzymes, creating imbalances not only in the food but in the person who eats that food.

Dr. Gio B. Gori, deputy director of the National Institute of Health's Division of Cancer Cause and Prevention, told the Committee, "The role of nutrition in human disease is obvious, and no other field of research seems to hold better promise for the prevention and control of cancer and other illness, and for securing and maintaining human health." As Life Scientists, surely we can say, "It's about time!"

Certainly we cannot long have a viable nation when its children and adults eat a diet well laced with cooked carcinogenic free-floating fatty acids. Dr. Gori said that there is a need to reduce the intake of foods rich in fats and specifically named meats and milk. Few people eat uncooked meat and most drink liberally of pasteurized milk (heated) which has a relatively high cooked fat content.

A report of the Worldwatch Institute, a Washington-based research group, states that "those with an affluent diet consume large amounts of animal proteins and fats in the form of meats and dairy products...and increasingly, they choose commercially manufactured foods over fresh, unprocessed products." It is well known that many of the commercially manufactured products are subjected to high temperatures destroying the normal fat content and rendering it less digestible. It is interesting to know that the fat-heavy American lifestyle is rapidly replacing the former heavy grain-potato-fruit-oriented diets of the countries throughout the world. In our earlier trips to Europe we became familiar with the small family-oriented markets with their beautiful displays of fruits and vegetables brought in early in the morning from the surrounding nearby farms and orchards. On more recent trips both to Europe and "down under" we have noticed fewer and fewer of these markets. They have been supplanted by supermarkets, a la U.S. style. These brightly lighted and beautifully appointed showplaces display a greatly augmented array of meats and the familiar over-processed devitalized foods so common in the American dietary. As our dietary practices expand so do the world's ills. Life Scientists should remember that fats are the most difficult of foods for the body to digest and they become even more dangerous when heated. Those persons who eat excessively of fats and especially of cooked fats, as in barbecuing and deep frying, place themselves in a hazardous position exposing themselves, as they do, to certain known carcinogens. We should eat as little fat as possible remembering that fat contains twice the food value by weight of all other types of food and, additionally, makes one vulnerable specifically to cancers of the uterus, breasts and prostate gland—in males.

The National Academy of Sciences has also noted that, in those countries where consumption is high of such foods as smoked sausages and fish, ham, bacon, frankfurters and bologna to name a few, that cancers of the digestive tract are also common. All of these products (we cannot call them food) are high in fat content and all are eaten after being subjected to heat. The presence of certain additives in most if not all of these same foods, such as nitrates and nitrites, with the subsequent formation of nitrosamines and polycyclic hydrocarbons, only adds to the health hazard of the fat.

And finally: we need so little fat! Just enough to pad and protect us. When and if we require additional fat, our amazing bodies can synthesize it from carbohydrates and proteins. Nature puts very little fat in man's perfect food, fruits, and that should certainly tell us something!

## **2.13 Cooking and Carbohydrates**

Carbohydrates are no exception. Cooking renders all starches indigestible. It was long believed and still is by most people, that cooking renders starches more digestible. The ability to digest starch thoroughly depends on the general digestive health of the individual. One person will experience no difficulty in digesting starch, cooked or uncooked, while another, with less digestive power, will be able perhaps to

digest cooked starch but will suffer from gas if he eats raw starch, due to fermentation of a residue of undigested starch.

Some scientists have maintained that cooking changes starch to dextrin and, since dextrin is easier to digest than the more complex molecules of starch, this was the rationale behind the assumption that cooking would render starch more digestible. True, starch will be converted and if it is maintained for a sufficiently long time. In ordinary cooking, only a very small percentage is so changed. Additionally, when we attempt to dextrinize food starch prior to eating, we interfere with the salivary amylase which normally acts in the resolution of starch. If starch foods are boiled and become saturated with water, the enzyme ptyalin, the active enzyme in saliva, will be powerless to affect any change from the poly to the disaccharide formulation, certainly a circumstance that will almost ensure fermentation along the alimentary canal, with the formation of such products as carbon dioxide gas, various alcohols and acetic acid (vinegar).

Eating cooked food causes persons not to masticate their food thoroughly. It is moist, giving the impression that it should be swallowed. The imperfect and short mastication time interferes with the digestive process along the entire alimentary canal due to the fact that the nerve communication channels are not kept open long enough to permit the inner stage to be pre-set in the three digestive departments in a correct arrangement before the arrival of the food requiring digestion.

On the other hand, the thorough chewing of food, and especially of starch food, gives sufficient time for message transmission and for adequate secretion of both enzymes and juices prior to the time of arrival of the food, resulting therefore in a more thorough resolution of the starch into primary molecules.

As a sidelight of interest here we might note that raw cabbage digests in two hours whereas it requires four hours if cooked. Most persons can eat raw cabbage, but few can eat cooked cabbage without experiencing distressing symptoms. We can note also an unnecessary energy drain on the system due to the extended time required for thorough digestion. If we desire health, we have to avoid such unnecessary energy loss.

Toasting and baking "to a nice brown color" forms charcoal (carbon) as well as other harmful products contained in the baking foods. Such products have been shown to have less food value overall than the soggy inside portions which have not been subjected to the high temperatures required to produce that nice brown color.

Phosphorus acts as a carrier to transport digested carbohydrates to the liver for conversion to glycogen which then can be stored both in the liver and in the muscle tissues for use in emergency situations. Adjustment of a proper intestinal pH to a rather strong alkaline balance is necessary for thorough and a more complete digestion of complex carbohydrates such as starch. The change in composition of the molecules after heating necessitates a different pH in a number of cases, not always possible for the organism to provide. Very high temperatures are required to change most sugars but the sugar in milk is changed in the process of pasteurization and is rendered less valuable, even though the heating temperature is relatively low.

## **2.14 Some Specifics**

Cooked starches are difficult to digest primarily due to the hydrolysis of the starch in the cooking process. The hydrolyzed starch is subject to easy fermentation giving rise to the formation of acetic acid (vinegar) and the other byproducts already mentioned. One of the harmful effects of acetic acid is that it has a tendency to leach out the body's phosphorus and to stimulate the thyroid gland. As we have previously observed in Lesson 39, there is an intimate relationship among all the members of the endocrine system so it is not a surprise to learn that, as the phosphorus becomes depleted, the performance of the adrenal glands becomes less perfect since phosphorus is one of the active components of the adrenaline hormonal secretion. Thus, we have dysfunction of both the thyroid and the adrenals and, no doubt, of other hormone-secreting glands.

It is little wonder that those persons who depend for a large measure of their substance on cooked starches so often experience headaches, throat congestion, mucous expectoration, pains in the heart, sour eructations, body odor, frequent chill and rapid pulse. It can most surely be said that such a diet, if long continued, will lead inevitably to hyperthyroidism and hyperadrenalism.

## **2.15 Cooking and Baby Formulas**

Oliver Wendell Holmes once said that "a pair of substantial mammary glands has the advantage over the two hemispheres of the most learned professor's brain, in the art of compounding a nutritious fluid for infants." Nature has provided an infant with an intestinal tract which will mature as the infant grows. This maturing process is a slow evolutionary process and, during the growing and maturing years, the diet must be fitted to the equipment provided and not the other way around!

At no time in the progress from birth to childhood to puberty to adulthood are the digestive organs designed to handle cooked food. The stools of an infant fed on the milk provided by a healthy mother will be soft, nonirritating, easily defecated and sweet-smelling. The stools of the young child, of the young lad or young woman and of the adult will remain always in the same, much-to-be-desired state indicating healthfulness when the constant fare is uncooked, well chosen, properly combined and eaten according to need. Why? Because we have the equipment within us to properly process food designed for the human body and also the equipment to dispose of normal metabolic wastes. It is only when we depart from the ways of body correctness that we begin to suffer from the effects of our departure and in a precise relationship to such departure. Anything cooked has changed in its chemical composition, its nutritive values have been deranged and the products of such change and derangement brought about by heat or by any other abnormal method, practice or substance, are always pathogenic. Cooking of the food supplied to an infant begins the wholesale destruction of health from the very first moment that food is eaten.

[Home](#) > [Lesson 43 - Cooking Our Food](#) > 3. Consequences

## **3. Consequences**

A high-protein diet plus overeating plus bad food combinations plus cooked foods plus animal fats, all cooked, of course, will always result in poor digestion, absorption, transportation, and assimilation. Such practices will result in excessive mucus, thickening of blood vessels and of the fluids, derangement of the lymph and blood fluids as, for example, an increase in viscosity (thickening), formation of plaques in the blood and concretions (accumulations of precipitated overload, as of uric acid, for example anywhere they may be dumped to get them out of the way, as in a joint); plus a host of other annoying and dangerous symptoms of systemic poisoning. All such derangements tend to alter homeostasis within the body.

We are not by design fat eaters, as we have said. The human body will meet most of its fat needs by synthesizing its own body fat from the sugars supplied by fruits. Remember that fat is composed of carbon, hydrogen and oxygen. Fruits contain exactly these same elements only in a different arrangement. The human body has the ability by means of catalytic enzymatic action to disorganize the sugars of fruits and then rearrange the released elements into the kind of fat which will suit its own specific needs at the moment. Fat taken as either an oil or as a solid fat presents problems at all levels and especially when it has been cooked. This kind of fat really just passes on through the stomach because that organ just can't process it. Fat is even very difficult for the intestines to manage, it is difficult to absorb and once it arrives at the liver, fat becomes a major concern to that organ, too.

Consider, in contrast, the sugar trip: almost no digestion required in either the mouth or stomach (it is all pre-digested and in a travelling molecular formulation), it is quickly absorbed because the molecular structure just fits into the membranous passage mechanisms and it passes easily through the cells lining the alimentary canal, it is greeted cheerfully by the liver which rejoices in a 90 percent gain of energy after fully discounting the energy loss of digestion, appropriation and assimilation and the transportation, and so proceeds happily to convert the sugars into glycogen for storage or to make the glucose available for the maintenance of body temperature and energy; and, if required, to restructure the primary elements into body fat. Thus, uncooked sugar-rich fruits are welcomed by the body while fats, cooked and uncooked, yield few, if any benefits to the organic domain.

### **3.1 Cooking, the Teeth, the Mouth, and a Forever-Young Face!**

There are two main considerations here, namely: the effect of heat upon the enamel of the teeth and secondly, the effect of poor mastication on the mouth and facial muscles.

The enamel on the teeth is a species of organic crystallization. It is by far the hardest substance in the human body, made by a precise magnesium-calcium arrangement. However, this crystallized material can be rudely cracked with hairline invisible fractures in the process of masticating very hot foods. These hairline fractures in time develop into dental caries. This may well be a significant cause of the high incidence of dental caries in this country, in excess of 98 percent even in children and almost 100 percent among adults, few of whom retain their full quota of teeth after the age of fifty, with many wearing dentures. Diminished health inevitably follows after the loss of teeth.

As to the second effect evidenced by poor mastication: cooking food encourages a person to masticate his food too little, to swallow it too fast, and to eat too much, all effects which have serious implications with regard not only to the health of the digestive apparatus because it is not well exercised and/or properly cleansed, but also to the general health of the entire body due to improper nourishment; but also to the health of the teeth.

When raw foods are eaten and eaten in their natural state (that is, unchopped, unshredded, and so on), the teeth are required to perform their full function and, as they regularly and dutifully perform, they are strengthened, just like any other exercised tissue, organ, or part. If they are not used properly, the teeth will weaken just as any other unexercised tissue, organ or part will weaken. Graham (Sylvester Graham, "Lectures") makes note, of the fact that if we become accustomed to masticating food only on one side of the mouth and do not make use of the teeth on the other side, within a very few years the unused teeth will begin to decay and the gums will become tender and, in time, a certain number of the unused teeth will be lost, while the teeth on the other side where chewing is performed consistently will remain sound.

Uncooked food, in contrast to cooked food, requires thorough mastication, especially when it is eaten without drinking any liquid during the mastication process (as it should be). Eating raw foods helps to cleanse the teeth and will tend to maintain a high level of dental health; but, not only sound dental health, but also the health of the mouth itself because full mastication of raw foods requires vigorous muscular exercise of all parts of the mouth including the tongue and all lymphatic tissues.

Whatever disturbs the function and causes a general irritability of the nervous system will lessen not only the health of the teeth, but also the health of the entire mouth. Insufficient mastication over the years gradually brings about a diminution of secretive ability. Saliva production falters as does enzyme production with a resulting lessening in the ability to process carbohydrates in the initial first stages so important to their complete digestion. If food is cooked to the soft, pulpy stage and is then consumed hot, tartar begins to build up on the teeth. The gums soon become soft, losing their tonus. The mucous membranes and muscle tissues of the mouth remain poorly exercised because all cooked food is so easily swallowed and people are deceived into thinking it is ready for the stomach, if they think about it at all. This imperfect mastication and insalivation obviously creates chemical and physical problems for the stomach and, indeed for the entire alimentary canal.

Muscles that are not well and consistently exercised become flaccid, limp and, if not exercised at all for a sufficiently long period of time, even atrophied. Many people today have wrinkled faces largely because they eat of so much devitalized cooked foods which they swallow so easily after insufficient mastication. Thus, they rarely, if ever, sufficiently exercise these facial muscles. About the only exercise they get is when the individual speaks and even then, the exercise is very limited and for too short a time to be of much benefit.

But, to the contrary, watch a true Life Scientist at his meals. He chews and chews and chews while all the while the saliva pours out, the teeth are cleansed and the gums, membranes and facial muscles participate fully and, in the doing, retain their elasticity and tonus, remaining forever young and wrinkle-free. Life Scientists do not require creams or lotions for facial plasticity nor face lifts to give the illusion of youth.

### **3.2 Overeating**

Eating cooked emasculated foods leads to overeating simply because a large quantity must be consumed to satisfy the system's overall nutritive requirements even though this is rarely accomplished in all particulars. Consequently most people who eat of cooked food are actually burdening their stomachs and other organs with three or four times more food than would be required to supply the same amount, if not more, of nutritive factors if uncooked foods were eaten and these in a more appropriable form. It is our belief that this one fact alone serves to drain the vital force reserves as the years go by because the mere quantity of food consumed requires energy and reserves for a time-consuming and more difficult digestion to take place, energy which might better be conserved and held in reserve for an extension of the life span. It is little wonder that drained energy reserves cause man's vitality to decline noticeably at forty and that only a handful of those persons who began life are still around at 70 when they should be perfectly capable of living heartily and in health probably far in excess of 100 years.

As Life Scientists we need to be aware of the fact that the usual food intake is not an index to the normal needs of the body, but rather to "the morbid cravings of a perverted appetite. The quantity of food consumed...is by no means a safe indication of the physiological requirements of the body...Civilized man lives to eat instead of eating to live...until after years of overindulgence, they find themselves in the grip of chronic disease.

Almost all students of this subject are in agreement that man has always had a tendency to overeat and that this tendency is, beyond all question, decidedly the greatest source of disease and suffering and untimely death to man. Even if we eat wholly of uncooked natural food, we must guard continually against this tendency. Countless numbers of experiments have proved, beyond a shadow of a doubt, that eating a minimum of food to satisfy systemic needs is a life-extender while eating in excess is a life and health destroyer.

Even if we eat wholly of uncooked natural food, we must guard continually against this common tendency, but obviously the danger is vastly augmented when an individual overeats on damaged food, food that has been cooked, its vital elements altered. Then, we break down, wear out and prematurely age all our organs and systems; our muscles stiffen, our bones become brittle and we begin to look curved, bent, wrinkled and old.

### **3.3 But I Like To Eat Some Cooked Food!**

Well, we tell our clients, "It's your choice!" We know that a high degree of heat applied to food for any length of time will greatly reduce its nutritive value. There is no argument here. We must decide if we will settle for less when optimum is best.

Not all of the value of food will be destroyed especially at lower temperatures. If cooking is done in a restrained fashion at lower temperatures and for only a brief period of time, so that the organic salts and other nutrients are not totally destroyed, there will then be no great harm in eating some cooked foods

*occasionally*, but let us be fully aware of the fact that when we do eat cooked food we will not be eating ideally nor will be providing optimum nutrient values to ourselves. We must remember that the quality of our body depends on the quality of the food we eat and upon how we eat it and, very importantly, on our restraint in eating.

Almost all artificial food preparation methods create a situation wherein we have a superabundance of one constituent or another, or else some are absent altogether or are present in too insufficient a quantity. The living organism always abhors an imbalance and reacts adversely to it, most often in the form of some diseased state in an effort to protect the integrity (the life) of the individual. Only uncooked plants, perfectly fresh and unspoiled, can provide the correct balance of known and unknown food factors to maintain perfect health. All wisdom dictates that eating any amount of cooked food represents a fool's paradise.

[Home](#) > [Lesson 43 - Cooking Our Food](#) > 4. Questions & Answers

#### **4. Questions & Answers**

**I would like to have you explain why it is that so many persons can appear to be so healthy in spite of the fact that they eat cooked food which, according to you, cannot long sustain life?**

That is a good question. You see, we all come into the world with an inheritance. It is our legacy from the past. Some of us have huge vitality reserves in our health bank account, others, less fortunate, have a lesser amount; still others possess a bare minimum to sustain life for only a short time. The greater vitality we have, the more value we will receive from the food we eat because our nerve energy allows for greater digestive efficiency. If our vitality has been reduced for one reason or another, we will not be able to digest, absorb, transport or assimilate nutrients with the same degree of efficiency. In time, our vital force will dwindle away and we will become more and more vulnerable; that is, subject to disease because we will become malnourished and enervated. Toxicosis becomes our companion, instead of radiant health.

**If we have always eaten mostly of cooked foods, can we change immediately over to eating raw foods entirely?**

I must give a qualified answer here simply because there are many variables to consider. Let me state firmly and without equivocation, however, that nothing but good can come by making a radical and complete changeover from eating all cooked food to eating all uncooked food provided it is food to which your body is adapted by structure and by function, namely, fruits, vegetables, a few nuts and edible seeds. However, not all persons can do so without being subject to certain psychological hang-ups and, if their bodies are quite toxic, to "withdrawal" symptoms of one kind or another. Age is certainly a determining factor. In our practice we find very few elderly people who can make abrupt changes without worrying unduly, even to the extent that their health is adversely affected by their emotional state. In such cases, it is our belief that until the mind has been reeducated, it is better to make changes more slowly. When persons are willing to fast, having come to an understanding of the benefits to be accrued thereby, then, of course, they should fast and following the cleansing of their body, they should immediately become "raw-fooders." But, let us emphasize that, all other things being precisely equal, nothing but good can come from introducing more uncooked food into the dietary regimen, even though the initial steps be small and hesitant. Keep at it. Your entire body will say, "Thank you!"

### **Dr. McCarter, what is life?**

I wish I knew. I'd probably win the Nobel Prize! But, seriously, no one knows this secret. It is locked up within all living creatures. We know certain things that happen within a living cell but we are just beginning to take our first hesitant steps across the membranous barriers via electron microscopes and radioactive isotopes but even our most liberal scientists admit that the inner world of life is still a vast unknown of maybe's and perhapses. Everything that is alive has the power to receive impressions and to react there—from or thereto; it also has the power to reproduce itself and, in the doing, to make certain that LIFE continues. Certainly we know when something is dead, without life; but, to spell out exactly what this phenomenon of life is and what makes it so, is beyond man's knowledge and probably will always remain the Creator's secret.

### **I always thought the acids in the stomach would destroy all life. Do not these acids destroy the "life" in food?**

Let me ask another question in answer to yours. The cells in the stomach, are they not alive? Of course, the answer is "Yes!" But, they are not destroyed by the gastric secretions. Food is not alive in this same sense. Uncooked food, however, should be capable of producing life if it is returned to the soil. For example, we can take a portion of carrot, place it in the soil, water it and see to it that it receives all the requisites of its organic existence and it will send forth leaves and grow. Raw food contains the food for life: enzymes, minerals, vitamins. In other words, uncooked foods contain the essence of life and it is this that is imparted to us when we eat of them and it is this essence that will sustain our own life in health.

### **If we eat always of raw foods from the day of our birth, will we live forever?**

Probably not. Lewis Carrell, a Nobel prize winner, a renowned physician and surgeon, proved that when cells are correctly fed and kept in a friendly environment with proper drainage of wastes, they could continue living and reproducing themselves indefinitely. Perhaps if man lived ideally and always under ideal conditions, he might also live indefinitely in health but it is doubtful that we will ever be able to live under such ideal circumstances. There are too many variables to guarantee life. We are all subject to physiological assaults of one kind or another and each one leaves an imprint, each one subtracts some measured amount from our vital force bank account.

### **You talk about our vital force bank account? Can't we use some of that vital force and then put it back by proper eating and living?**

Probably not. Once used, it cannot be replenished by changing our ways and assuming a more correct lifestyle. However, this does not mean that all is lost. By no means. We will no doubt have a diminished supply of vital force, but we can, by constructive application of principle and devotion to the sacredness of life, learn to use our vital force more efficiently. Most people dissipate fully two-thirds of their quota of vital force by the time they reach the age of thirty but if they learn how to live correctly and to eat foods adapted to the human structure and how to eat that food and to see to it that they eat a minimum (adequate) amount of food, then they will extend their life span far beyond those who continue the common pattern of living and eating.

### **You talk about using our vitality more efficiently. What do you mean by this and how can we do it?**

Let me give you an example. Foods have differing orders of digestibility and it is interesting to know that those foods that are most easily and thoroughly digested are the foods that are

best for our health. When we eat a meal which contains meat, potatoes, bread, butter, a vegetable or two and then top it off with a rich dessert, such a meal and its remains after the digestive process has been concluded may remain in the alimentary canal for several days, especially if more food is eaten during the day. This is the common practice and it is exceedingly wasteful of energy because the digestive organs and glands are required to work at full capacity for hours on end trying to cope with such a heterogeneous mixture of food. But, to the contrary, when we eat mono meals, say of fruit, the food will be in and out of the stomach in less than an hour in most cases, and the entire trip from mouth to anus will be travelled and the residual wastes disposed of in less than 24 hours, often in half that time. Can you imagine the savings of energy to say nothing of the increased efficiency of digestion obtained by eating only those foods which are best adapted to our digestive equipment? We conserve our energy in order to live long and in health.

**I had always been told that raw foods contained molds and germs and that this is why it is better to eat of cooked food. Can you address this issue?**

Gladly. Germs and molds are made up of protein. They will be digested in the stomach just like any other protein. The only time they will be able to gain a foothold in the digestive canal is when it becomes highly toxic. Then, they find a smorgasborg of food laid out before them and ideal conditions under-which to live. They will, of course, become fat and healthy, reproduce rapidly adding their own toxins to those already present, placing their host's well-being in jeopardy. But, in the normal (and we mean really normal as in "healthy" person, they will simply be digested. Incidentally, the only way to rid the intestinal tract of unwelcome pests is to remove their food supply since all living things require food. The best way to do this is to fast using only distilled water to satisfy thirst.

**Should a person never eat any cooked food?**

If a person's stomach is highly inflamed due to past indiscretions and perhaps filled with mucus and catarrh, then he may have to continue eating cooked food but his meals should be simple ones, if he eats at all. It would be far better to have such a person, fast until his alimentary tract has been both cleansed and health and then introduce raw foods one at a time, reeducating his digestive tract and his mind to accept this new way of eating. With older persons who are afraid to fast, we lay out menus to follow which are, at first, made up of all cooked food properly combined and then proceed to introduce more and more uncooked food. We have great success using this approach. They especially seem to adapt well to lightly stewed or baked fruit for their first meal as, for example, a baked apple. After a week or two, we then show them how to make a date sauce made in a blender using raw dates and distilled water which they then pour over their baked apple. They usually accept this combination well, both mentally and physiologically and by their acceptance and enjoyment of this one dish become more receptive to our next suggestion! As they watch their health improve, they often become completely converted and eat nothing but uncooked food.

## **Article #1: Uncooked, Unmixed, Unseasoned Food by Dr. G.R. Clements**

Multitudes are discovering that their diet is wrong, and many of them are turning to the medical doctor for dietetic advice. Dr. Willian says that this course is absurd. He observes:

"The laity took to the doctor, and the doctor is usually a dietary dunce. He knows not how to feed himself, or else he does not practice what he knows. He eats of all the far-fetched, overseasoned and otherwise dietetically abominable dishes, sheds his teeth, hair, and healthy color quite as young as any of his patients, and is a confirmed and incurable dyspeptic at 35. His medical societies and his clubs all spread a "collation" after each meeting—salads, cake, cheese that would make a tanyard smell like a rose garden, sandwiches with sliced sow in the middle, to be topped off with claret punch, capsicum-flavored gingerale and Cuban-Connecticut cigars."

Since it has required time for the body to adjust itself to the use of cooked, mixed and seasoned foods, it will require time for it to recover from this habit, and readjust itself to the use of uncooked, unmixed, unseasoned foods. In fact, it is practically as difficult for the body to repudiate a destructive habit, as for it to resign itself to such habit, as wide experience shows. But there is this difference: since the body suffers a gradual decrease of vitality as it adjusts itself to a destructive habit, so it experiences a gradual gain in vitality as it discontinues a destructive habit.

Evidence to prove the truth of this last statement may be had by him who will diligently test the proposition. I daily receive letters from patients, who under my advice are adopting the uncooked, unmixed, unseasoned diet, in which letters the patients happily declare that they are having a delightful improvement in their health, since adopting this mode of eating.

Bread, butter, milk, meat, eggs, potatoes, coffee, tea are the staple articles of diet of this country. Medical schools raise no voice in protest against this menu. It is the diet of medical doctors and medical hospitals, and the medical profession teaches that this is the standard diet, and must be eaten in ample quantities by all who crave vim, vigor and vitality.

Medical institutions forget that the camel, elephant, rhinoceros and hippopotamus never eat these things. They forget that the dinosaur, megalosaur, magatherium, and mammoth, the mightiest beasts that ever roamed the earth, were herbivorous and frugivorous animals. They forget that great athletes of ancient Greece and Rome were trained on a diet of vegetable and fruit; that Milo the Greek, perhaps the strongest man of history, was a disciple of Pythagoras, and a strict vegetarian. They forget that the giant gorilla feeds on fruits, berries, and herbs, and yet is so powerful that no animal of the wild dares attack him.

Clements Willian further observes:

"Where do we find such muscles of steel and rubber as are those of the agile antelope and the equally agile deer, that run with the wind for a day and a night without tiring? Or where the equally keen sense of sight, hearing, and smell; where such sleepless sharpness of instinct, such tenacity of life, such graceful and perfect physical development? The huge elephant, with the strength of a steam engine, and an intellect that lacks only the faculty of speech to make him a talking philosopher, lives half a dozen centuries, practically on grass. This is not at all strange, when we stop to consider that, botanically, all grains are grasses."

George Hackenschmidt, the greatest wrestler known as the Russian lion, weighing 220 pounds of bone and muscle, toured the world, throwing the huge Greek and Turk wrestlers without difficulty. Of his diet Dr. Bernard remarks:

"His breakfast consists of fresh lettuce and five or six Brazil nuts. The Brazil nuts and some sweet fruits are the only really heavy foods that he eats. All his other meals are composed of fresh fruits and fresh vegetables, eaten raw."

Even here the law of diet is violated, for we find man mixing lettuce with nuts. If we desire perfection in diet, we must strictly adhere to the one-thing-at-a-time, rule.

We hear our students asking: Since you condemn all the menus published by the various authorities, what sort of a diet would you prescribe?

That question forces us to declare ourselves. But our prescription is so simple that a child cannot go astray in following our directions. It also offers a complete solution of the food problem, and still is so elementary that few will consider it worthy of attention.

Go and wash in Jordan and be clean, has never appealed to humanity. It is too simple. Men are looking for signs and magic. The plain and simple are of no value, for these one can understand without education. They forget that the object of education is to lead men away from the truth into error, confusion and complexity, and there leave them lost and bewildered.

Our diet prescription is this; Eat whatever you want to eat, whenever you want to eat, but observing these three fundamental rules:

1. All food must be uncooked;
2. All food must be unmixed;
3. All food must be unseasoned.

Think of the time, toil, worry, and wealth that would be saved, if people would be persuaded to return to his ideal eating method of primitive man, whose height was like the height of the cedars, who was as strong as the oaks...and who lived to see the sun rise and set" for nearly a thousand years, ere his sturdy frame sank back again into the dust whence it came.

With one sweep of the pen we solve the perplexing diet problem, and if our advice were heeded, human health would improve so amazingly in a generation as to be one of the wonders of the world.

*From Lesson 21 by Dr. G. R. Clements in Orthopathy The New Science of Health and Natural Healing.*

[Home](#) > [Lesson 43 - Cooking Our Food](#) > Article #3: Excerpts From Nutritional Methods Of Blood Regeneration, Part II by Dr. R.W. Bernard

### **Article #3: Excerpts From Nutritional Methods Of Blood Regeneration, Part II by Dr. R.W. Bernard**

Sherman emphasizes the "protein-sparing" action of carbohydrates, and also refers to the synthetic formation of protein within the body by the formation of simpler amino acids, as analine, by union of glucose with ammonia, a protein metabolic end-product. From the simpler amino acids, he claims that more complex amino acids can be synthesized. An abundance of glucose will therefore aid such protein synthesis within the body, whereas, on the other hand, when there is a lack of carbohydrates and fats, protein molecules will be broken down to yield carbon compounds.

Kayser compared the efficiency of carbohydrates and fats as spacers of protein by observing the effect upon the nitrogen balance of replacing the carbohydrates of the food by such an amount of fat as would furnish the same number of calories. On substituting fat for carbohydrate there was a marked increase of protein catabolism, with corresponding loss of nitrogen from the body; this loss of nitrogen,

accompanied by a negative nitrogen equilibrium, increased each day that the fat diet was continued, but stopped as soon as carbohydrates were added to the diet, when the body almost at once began replacing the protein it had lost, although the nitrogen and calories of the food were practically unchanged.

Taliquint, working in Rubner's laboratory, also found that if one-third of the total value of carbohydrate in the diet was replaced by fat, there was an unfavorable influence on the nitrogen balance, causing a small fall of body protein. Sherman, in his "Chemistry of Food and Nutrition," says: "It appears that the carbohydrate of the food cannot be entirely replaced by an equal number of calories in the form of fat without an unfavorable effect upon the nitrogen balance."

[Home](#) > [Lesson 43 - Cooking Our Food](#) > Article #4: Excerpts From "Unfired Food And Tropho-Therapy" by Dr. George J. Drews, A.I.D.

### **Article #4: Excerpts From "Unfired Food And Tropho-Therapy" by Dr. George J. Drews, A.I.D.**

The Unfired Diet is truly attractive,  
Is moral, aesthetic, delicious and good,  
And further than this, it is more than preventive -  
It cures the disease that come from cooked food.

Cheer up sisters and brothers and rejoice with me for I have found the key that unlocks the door to physical, mental, moral and spiritual salvation and I will tell you how to use that key if you will but listen.

Those who are seeking for absolute health, longevity and refinement should understand that THE BODY, MIND, SPIRIT AND SOUL ARE ABSOLUTELY INTERDEPENDENT.

Hence there is no sane mind, no spiritual perfection and no salvation of the soul without a healthy body. A healthy body can only be built and maintained with Nature's perfect (unperverted and unfired) food, pure water, fresh air, sunshine, exercise, restful sleep and a serene mental attitude savored with lofty aspirations.

It has been the earnest aim of the author to reintroduce a natural health-sustaining, disease-resisting, disease-eliminating, brawn- and brain-building diet consistent with the present state of human evolution, civilization and refinement. A diet which shall promote further evolutionary progress on all the planes of the body, mind, spirit and soul. A diet physiologically and financially economical, artistic, inviting and delicious. All logical minds will agree with me that this can only be accomplished by feeding on natural food which contains all the elements for building a healthy body and which promotes all the natural functions of life.

Here it must be understood that cooked food is not natural because its chemical constitution is changed (perverted) by the destructive power of the applied high temperature. The sun energy (galama) is dissipated. The volatile essences are exploded. The tonic elements (organic salts) have been freed, mineralized and neutralized. The proteins are coagulated. The starches are rendered so soluble that they enter the circulation undigested. The atomic arrangement of sugar is rendered incongenial. And the oils are fused. Therefore cooked food readily ferments and decays in the alimentary canal; besides, its consistency does not give the proper exercise to the organs of cominution, digestion and absorption; and it has a tendency to puzzle, confuse and pervert the alimentary functions, thus laying the foundation for disease.

Natural unfired food promotes all natural functions of the body. With natural foods, only, can be laid the

foundation for the maintenance of a truly healthful and beautiful body, spirit and soul. By means of unfired food can Nature keep the body clean, heal all diseases of body and mind and eradicate immoral tendencies. It is unnatural food which interferes with the natural metabolism of the system, which hinders and perverts natural growth, which retards recuperation and reconstruction, which results in anemia and atonicity, which promotes disorderly proliferation, which causes abnormal craving and inebriety and which results in nearly all the physical, mental and moral diseases and pains which ignorant, misinformed, deluded, ensnared and perverted humanity is heir to. Every attempt to improve on natural food by artificial means results in an absolute failure—it cannot be done.

Every unnatural thing or action in the realm of nature has inherent the cause of its own destruction. Hence for every infection and malfaction nature has an acute reaction (crisis) which results in salvation for those who obey her laws; but interfere with that acute reaction by means of medicine or surgery, and it may disappear only to reappear in a later chronic or fatal reaction. "Interference perpetuates both good and evil" hence—"Resist not evil."

There is a "Beneficent Design" in unperverted Nature, but also a malefic design in perverted and artificial Nature....Natural food, fresh water and live air in connection with plenty of sunshine, exercise and rest, is the only reliable "Materia Panacea."

[Home](#) > [Lesson 43 - Cooking Our Food](#) > Article #4: Excerpts From "Nature—The Healer" by John T. Richter, Vera M. Richter

#### **Article #4: Excerpts From "Nature—The Healer" by John T. Richter, Vera M. Richter**

*Excerpts from the "Biography" given to introduce the subject of the influence of eating raw foods on health in NATURE—THE HEALER written by John T. Richter and Vera M. Richter. The writer in this excerpt is Mr. Richter. Date, October, 1936.*

After having lived for fifteen years largely on a cooked food diet (no meat, of course), I noticed that there was something physically wrong with me. My kidneys were not functioning properly. I seemed to lack recuperative energy. Although I did not feel ill enough to be in bed, I was constantly harassed by a "gone" feeling, lack of power to rebuild myself—in short, general lack of energy. Especially was this forced upon my attention once when I was called out into the country on a consultation. I was practicing independently at that time in Minneapolis. It was a long, hard trip—thirty miles over the prairies, and back to the city only at four in the morning. It was too late to have any real rest in bed, as I thought; therefore I simply waited around until it was time to have breakfast. Then I went to the office to get ready for business. The patients were already coming in, but I was so tired that every now and then I would find myself dozing over my work. I would shake myself, take a swallow of cold water, and rub cold water over my face. Yet in a moment or two I would again be nodding. I was nonplussed, not to say alarmed, at this lack of reserve energy. I became dizzy, too, at intervals. What was there in my system of living that was wrong? Had I not at least been eating correctly? That set me thinking.

It was not, however, until later that I became convinced it was really the food I had been eating which was at fault. This is how it came about: in a naturopathic magazine which had come to my hands, there was an article describing how a certain Dr. Lust had been invited by Dr. George Drews of Chicago to partake of an uncooked food dinner. It told of the many different varieties of food that, were served, of how delicious they were. It said something, too, about raw pie. I thought, "How curious, unbaked pie!" I remembered how mother used to make hers. But this was raw pie. The whole idea took me by surprise. How can people live on uncooked food, I wondered, just as people today ask me the very same question.

I kept thinking about it, however, and finally decided to give this new diet a trial, to see if it would bring me that unlimited reserve of energy which I so ardently desired, as well as freedom from the more obvious diseases. Dr. Drew came to Minneapolis to teach me, as well as the class I had organized for him. Gradually, my health began improving, as the result of faithful adherence, one hundred percent, to the prescribed diet. In six months such a change had been wrought in my body that it seemed logical to use the new system in my practice in order to observe how it would affect others. After a period of nine months, I realized that the nature of my bloodstream had been completely transformed. My blood, under tests, had previously shown too much acid present. Now it had become slightly alkaline, which is the normal state for one who is in first-rate health. We now know that cooked-food vegetarians, as well as meat eaters, alike suffer from too much acid in the bloodstream as a rule. Nine months had been required in my case, but many others require only from three to six months. You can well suppose that I was very happy when I found my blood was sufficiently alkaline. What a mental relief and assurance to know that I was getting better at last! As to weight, when I first began, my 145 pounds dwindled away to 123. Many of my friends told me, as yours will undoubtedly tell you, that I had better quit before starving to death. Yet, realizing that my old, worn-out body cells had to be utterly eliminated before new cellular tissue could take their place, I remained faithful to my task. All the while, of course, even though seeming to be thin, I felt much better than I ever had before, and really did not care whether the scale index went up or down. Soon I redeemed that loss—redeemed every pound and a little additional.

For many years now I have lived according to this system. I was in the late forties when I started. Today, at 84 (I was born in 1864), I am active and without disabilities of any kind. No aches or pains have plagued me for many years.

### 1. Foreword

Eating seems to be the favorite indulgence of humans—it has no rivals. It is part of, or associated with, or on the periphery of, almost everything he or she does. It is the accompaniment, passtime, recreation, entertainment, hospitality, ice-breaker, social function, reward, goal, comfort, business tool, monotony-relief, grief-assuager, pain-reliever. Humans eat when they work, they eat when they relax, they eat when they rest, they eat when they watch, they eat when they listen, they eat when they ride.

They eat, not necessarily because they are hungry, but—because it is meal-time, break-time or snack time because they are bored, restless or unhappy; because they need something to do while waiting, while watching television or movies, or while playing cards; because they can't offend the hostess; or for no reason at all.

Intervals between eating become shorter, the habit of chain-eating abounds and we may find them

tasting, chewing, snacking, eating, any time at all, from the first thing each morning till the last thing at night.

They know that their digestive equipment must serve them for their lifetimes, but they make little or no effort to economize on its use, or prolong its ability to function. They rarely give it a vacation; they even force it to work while they sleep. When it complains, they stifle it with drugs. When it breaks down, the surgeon may cut out the offending tissue—perhaps fifty or sixty percent of the stomach, ten or fifteen feet of the intestine, or maybe part or all of the colon.

The most significant cause for these conditions is the combination of sedentary habits and dietary errors (*especially overeating*).

*Overeaters of the world (you comprise the majority)*—I hope I can help you before you reach the point of no return.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 2. Quintessence

## 2. Quintessence

"The smallest amount of food able to keep the body in a state of high efficiency is physiologically the most economical, and thus best adapted for the body's needs."

*This is the Chittenden concept, stated years ago by Russell Henry Chittenden.*

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 3. "Appetite" Is Not Hunger

## 3. "Appetite" Is Not Hunger

"Appetite" is a habit and as such can be trained to be satisfied with small amounts of food, or to demand enormous amounts of it. The English poet, John Dryden, said, "we first make our habits, and then our habits make us."

Many people have never emptied the stomach completely. Most people have never experienced true hunger, which is a mouth and throat sensation, and not a feeling of emptiness and weakness.

People eat—either from habit or because they feel better, or stronger, and—frequently—because the food relieves distress or pain. The food has a stimulating effect, and forces the body to get busy dealing with the newly-swallowed food supplies. It must, perforce, temporarily discontinue its efforts to clean out the debris left by previous meals—which efforts have been the source of the discomfort.

Waste material from the new food adds to the organism's need to clean out the debris (which can be accomplished only by not eating—by fasting).

Dr. Claunch says (*The Hygienic System, Volume II*, p. 291), "The difference between true hunger and false craving may be determined as follows: when hungry and, comfortable, it is true hunger. When hungry and uncomfortable, it is false craving. When a sick person misses a customary meal, he gets weak before he gets hungry. When a healthy person misses a customary meal, he gets hungry before he

gets weak."

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 4. Development Of The Habit Of Overeating

#### **4. Development Of The Habit Of Overeating**

The development of the habit of overeating starts all too early. The sad truth is that children are trained to overeat. From early infancy, babies are coaxed to take frequent feedings they do not need. Older children are bribed to "clean their plates" with the promise of a sweet dessert, which further complicates the digestion of the unnecessary meal. Worst of all, they are not even allowed to refuse a meal when they are not hungry.

Even the sick are urged to eat "to keep up their strength"—in spite of the protests from the ailing organism. Young girls are taught that the way to a man's heart is through his stomach. *The way to a man's health is also through his stomach.*

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 5. Overeating Undermines Health

#### **5. Overeating Undermines Health**

Overeating is probably the greatest culprit in the undermining of our health. It is the primary cause of most digestive problems, and impairment of the digestion leads inevitably to the breakdown of the organism.

R.T. Trall, M.D. (*Digestion and Dyspepsia*, pp. 82-83) said, "It is a great mistake to regard dyspepsia as peculiarly or especially a disease of the stomach." He said that a multitude of organs and structures are essentially cooperative in the digestive processes, and they are just as co-implicated in the derangement of these processes.

"The debility of the stomach or other digestive organs, in any case of dyspepsia, is no greater and no worse than that of all other parts of the body. Indeed, the difference is just the other way, for nutrition, being the first and last process of organic life, all other parts of the system are disproportionately debilitated when the digestion function is impaired. Dyspepsia is, therefore, but a name for universal physical deterioration....The error of regarding dyspepsia as a local disease instead of a constitutional infirmity, leads to the mischievous practice of local medication." (Stimulants, tonics, nervines, opiates, purgatives, etc.) "These are excellent methods for curing dyspepsia by killing the patient, or to mitigate symptoms by destroying vitality.

Laboratory experiments have demonstrated repeatedly that overeating is a major cause of cancer. The following experiment has been repeated hundreds of times at various research laboratories; many times at the finest cancer research institute in the world. One hundred rats are bred to develop breast cancer by the age of one year, then separated into two groups. One group is given free access to food, the other group is given the same food in limited amounts. All rats in the first group develop cancer, but only 20% of the rats in the restricted food group develop cancer.

Conventional diets and overeating (or even overeating of the best foods) result inevitably in damage to the organism. The body is forced to make adaptations, and to gradually increase its tolerance of toxins, bringing it closer to common digestive maladies, followed by impairments of the entire organism.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 6. The Remedy Mentality

## 6. The Remedy Mentality

The victims of the uncomfortable symptoms thus produced develop a "remedy mentality," and are always seeking new preparations, medicines and cures (as an easy way out).

Food is used for the relief of symptoms. Ulcer patients are fed frequently during the day and sometimes at night; nervous people are fed to quiet them. "Foodaholics" (compulsive eaters) suffer from nausea when their stomachs are empty and must have more food.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 7. How Overeating Vitiates The Body

## 7. How Overeating Vitiates The Body

Sylvester Graham used to say, "A drunkard may reach old age, a glutton never." And Hippocrates also said, more than two thousand years ago, "Excess in drinking is almost as bad as excess in eating."

Remember that we require less food—and can utilize less food—as we grow older; and that overweight becomes a greater threat with the passing years. Excess poundage not only increases the threat of coronary problems, diabetes, and a host of other degenerative diseases—obesity will undoubtedly shorten one's life.

Dr. Shelton says that overeating overworks and poisons the body. Overindulgence in food works all the organs of the body to death and wrecks the whole system long before the digestive organs begin to show signs of weakening. Don't labor under the delusion that unless food causes distress in the stomach, it produces no harm.

In the overeater, all the functions of the body are conducted more rapidly than they should be until the overwork forces them to stop. Light eaters who use no stimulants should have a heartbeat (pulse) of about sixty a minute. The average of seventy-two that is considered normal is too high, and is the average standard for over-stimulated, overfed individuals.

*Cornaro's food selection is not one that we would recommend, but the point here is not the particular food items but the quantity of food ingested that resulted in his longevity, ed.*

## 8. If You Want To Eat More, Eat Less

It is obvious that reduction of total food intake will prolong the life of all the vital organs by reducing their work loads. Dr. Graham said, "It is a general rule strictly true that a correct quantity of a less wholesome ailment is better for man than an excessively small or an excessively large quantity of a more wholesome ailment. It is solely from the want of a proper regard for this important truth, that many have been unsuccessful in their attempts to live exclusively on a vegetarian diet."

A well-known illustration of this precept is the example of Luigi Cornaro, who lived to about 100. As a young man (around forty), he became very ill, and an early death was predicted. He discontinued his gluttonous habits and experimented with various foods to find which foods caused no overt symptoms. He restricted himself to fourteen ounces of food daily. He ate bread, meat, the yolk of egg, and soup (a selection of foods which caused no symptoms). The quantity was minimal, you will agree, and so his body was able to handle it efficiently and sustain itself so well that he outlived his prognosticators.

Cornaro said that what we leave of a hearty meal does us more good than what we have eaten. He is credited with having said (loose translation), "if you want to eat more, eat less, because if you eat less, you will live longer, and if you live longer, you will eventually eat more."

Hereward Carrington (*The Natural Food of Man*, p. 269) quotes Dr. Nichols: "It is my experience—and I believe of many others who work as I do—that the less I eat, the better I feel. I do not vary much in weight through months and years from 160 pounds. In solid, dry weight, my food, day by day, would not exceed ten or twelve ounces."

## 9. Light Eaters Vs. Heavy Eaters

The light eater has muscles of better quality, and his strength and endurance have been repeatedly shown to be greater. He thinks more quickly, more accurately and clearly, has more reserve power, and lives longer. He also escapes the aches and pains that (sooner or later) fill the lives of heavy eaters. (Dr. Shelton, *Human Life, Its Philosophy and Laws*, pp. 240-241.)

Temperate eaters have good digestions, and never think about their stomachs. Heavy eaters are troubled with thirst, bloat, acidity (and all kinds of disorders), and are constantly "popping pills" to obtain relief (spelled R-O-L-A-I-D-S).

Sometimes, overeating may produce an appearance of health, with no overt symptoms (as yet!), and a well-rounded appearance, but it cannot compare with the strong, enduring, true health of the properly nourished body.

## 10. The General Rule

Carrington maintains that overeating is the chief cause of all disease and thus shortens and destroys life. He says that the general rule to follow is: "Every individual should restrict himself to the *smallest* quantity that he finds, from careful investigation and experiment, will meet the wants of his system—knowing that whatever is more than this is harmful.

A high caloric intake produces a toxic body, which is unable to use energy efficiently. Waste clogs the body, impairs normal function, and demands high blood pressure for circulation. The more food that is ingested, that much more must be eliminated. If more is ingested than the body is able to utilize efficiently, a great deal of the body's energy is wasted in converting and expelling the surplus.

## 11. Building Health And Strength

Many physical workers and athletes think they must eat excessively to maintain strength and endurance—but the result is premature aging.

Professor Gilman Low demonstrated the ability of the body to build and maintain Herculean strength and great endurance on little food. He trained for two months. For the first five weeks he ate one meal a day, almost all uncooked foods. During the last three weeks he ate only four meals a week. In fifty-six days of training, he ate forty-seven meals. After the first five weeks of almost all uncooked foods, he ate eggs, whole wheat bread, cereals, fruit, nuts, milk and distilled water.

Eleven hours after the last meal, he lifted 1,000 pounds 1,006 times in 34 minutes and four seconds. Fifteen minutes later, he lifted one ton 44 times in four minutes.

The preceding details about Professor Low's spectacular feat is given in Dr. Shelton's *Volume II*, pp. 285-286, but no information is included on the date this occurred, the height and weight of Professor Low, and whether or not he was a professional weight lifter.

This was an impressive demonstration of the fact that health and strength can be maintained on minimum amounts of food, but, in general, Dr. Shelton says, "It is quite true that a man needs more protein while he is building large muscular bulk, and he perhaps needs a little more protein than the average man to maintain so much muscular structure, but it is a fallacy to think that he needs and can use as much protein as is consumed today by men who train with weights." (*Dr. Shelton's Hygienic Review*, March 1974, p. 161.)

On the other hand, it is true that there is an important relationship between activity and the amounts of food that can be efficiently processed by the organism. The combination of sedentary habits and dietary errors, especially overeating, will inevitably lead to disease. Active people, who make vigorous activity and regular exercise an integral part of their lives, are better able to process the food that they eat—to reap the benefits—and even to discard undesirable substances and excesses.

Dr. Shelton says (*Dr. Shelton's Hygienic Review*, March 1974, p. 150), "Excess of food is often but another term for a lack of fresh air and exercise."

## 12. Willpower Is Supported By Knowledge

Willpower is not the only weapon in the fight to break the habit of overeating. Knowledge is a much more potent tool.

The individual must realize and acknowledge that overeating is a habit that has him or her in its grip. If one is eating denatured foods, which do not completely nourish the body, such foods may not satisfy hunger unless eaten in large quantities. Spices, condiments and cooked foods also result in stimulation of appetite and overeating.

If the change to a good selection of foods has been made, but a great variety of foods are being used at a meal, this also leads to overstimulation of taste and appetite—and overeating.

## 13. Food Addiction

People become overweight because they overeat. They may overeat because they are overtired, unhappy or bored. Some individuals overeat because of psychological and emotional factors—such as compulsive eating as a compensation for frustration, defeat or loss. Anxiety and a poor self-image are so uncomfortable that relief is urgent.

Food reduces the energy level in brain and thus relieves anxiety and depression.

People overeat to satisfy these emotional needs which translate into vague cravings which seem to be never satisfied.

Or they may be overeating because of poor mastication, stomach enlargement due to a history of overeating, or because their inadequate diets leave them physiologically unsatisfied. The result is food addiction.

Any type of addiction—be it addiction to sugar, salt, condiments, coffee, tea, chocolate, alcohol, tobacco, drugs, vitamin pills—or even food in general—inhibits pancreatic efficiency, and pancreatic efficiency has a relationship to both low blood sugar (hypoglycemia) and high blood sugar (diabetes). William Phillpott, M.D., specialist in cerebral allergies and psychiatry, says, "Addiction is dangerous, because it suppresses pancreatic function."

Mehl McDowell, M.D., says that irresistible cravings for food can be understood as the typical cravings of addicts, stemming from cyclic biochemical processes. The addiction can be made to temporarily disappear in several days after totally avoiding the foods to which the individual is addicted. The addictive food will frequently be one or more in the sugar/white flour group, but it can be any foods, which, when discovered, are "enemy foods" for that person.

Dr. McDowell says that total abstinence from the "enemy foods" is only the first phase, which must be followed by a "conditioned reflex response"—the "instant yuk technique." The person trains himself to react with disgust to thoughts about the "enemy foods." (See article "Say Goodbye to Compulsive Eating," in this lesson.)

Once the addiction is under control, even overeating syndromes with psychological bases can be more easily restrained.

## 13.1 Binging

Binge eating is the way that bingers cope with life's problems, and this may contribute more to overweight than any other factor. Binge eaters may compulsively pile in hundreds, or thousands, of calories, almost without any true realization, satisfaction or enjoyment. They are trying, unsuccessfully (perhaps unconsciously) to escape from reality. Some people drink, some use drugs, some go on shopping sprees—and some eat. They usually eat rapidly, as though fearful they will be deprived of the mountain of food.

## 13.2 How To Escape From The Slavery To Overeating

An article in "Food for Thought"—a brochure found in health food restaurants—suggests, "With or without outside help," (the best is Overeaters Anonymous), "the binge eater can learn to apply some principles of behavior modification. First, binge eaters must learn to pay attention to what's happening at the start of the binge—the time of day, where they were, what they were doing, what they were thinking, what they were feeling. It helps to keep a daily log or diary. Second, they must analyze what they discover. Divorced individuals might find, for example, that the binge usually occurs in late afternoon when they become acutely aware that the former mate won't be coming home to share the evening meal with them.

"And third, they can learn to break the chain. In the example we just used, the individual could make a point of being somewhere else in the late afternoon—the library, an early movie, a gym or an adult education class, for example. Learning to control binge eating is difficult, but not impossible, and it's worth the effort."

The individual must *work* to initiate whatever changes are necessary for release from slavery to the appetite; that will help to break the habits of unwholesome redundancy which are threatening physiological, efficiency. When major sources of former eating pleasure are eliminated, they must be replaced by a new eating style that can gradually grow to be even more pleasurable, and by a new life that can be psychologically, emotionally, mentally and physically rewarding. The individual must be encouraged to not concentrate on what is being given up, but rather on what will be gained.

The body chemistry is influenced by the food that is eaten. When the diet is altered and the new diet maintained for a given length of time, the enzymes, body fluids, and glandular secretions become increasingly adapted to the influences and requirements of the new food program, just as the organism necessarily struggles to adapt, when it is bombarded with junk food, or too much of any kind of food. *The important difference is that the prior adaptation to the misguided food program involved health deterioration, while the readjustment in the direction of an ideal food program is towards improved health.*

We are not referring to calorie restriction in the usual sense. Reducing diets are always frustrating and frequently unsuccessful, since they involve countless decisions and the exercise of power at every meal. It never becomes any easier to eat half portions and to refuse the dessert, because the reducing diet continues and accentuates the perverted tastes and cravings of the malnourished (even though adipose) body.

Rather, we are referring to a planned program of meeting all of the body's nutritional requirements in a pleasant, satisfying, rational manner, with no redundancy or surfeit, which will tend to gradually reeducate perverted appetites—and produce such a sense of well-being that cravings will become easier to handle, and gradually all but disappear.

Ideally, such a program should be preceded by a thorough indoctrination into the precepts of the Hygienic system. The initial period will require mind control and firmness of purpose—but the potential rewards for those who have the determination to succeed are almost incalculable.

The first thing to do is to determine one's goal, make plans, and don't stop until success is attained.

Those who stumble along the way should pick themselves up, forget about the fall, and keep right on going. The only failure is giving up.

Learning to do something—to drive, to play a musical instrument—takes many hours of practice, and so many mistakes!

### 13.3 Forming New Habits

It is not easy to break a habit. At first, you may dislike or even hate what you are trying to do. Tough it through! Soon it won't seem so difficult and the worst part is over. But the best is yet to come, and you will eventually experience the delights of good food and good health.

A simple approach to the whole problem of overeating is the elimination of cooked food to the greatest extent possible. It is difficult to habitually overeat at meals when no cooked or processed foods are served. (However, snackers *can* overeat, even of uncooked food.)

John M. Douglass, M.D., internal medicine specialist at Southern California Permanente Medical Group (in his reports in the *Medical World News* and the *Annals of Internal Medicine*) says that raw food diets reduce or eliminate the need for insulin in many diabetics, reduce blood pressure, and develop an inner feeling of cleanness that causes people to want to reject such habits as smoking, drinking and overeating (from *Organic Gardening Magazine*, July 1978).

### 13.4 A Practical Program

A very practical program to eliminate the over-consumption of food is to begin with a short fast (about three days), followed by a program of twelve meals weekly—a thirty-six hour fast one day out of seven, and two meals a day on the other six days—with probably one meal around noon and the other in the early evening—no snacking.

Most people do well on such a program. Occasionally, we find a person who tends at each meal when he is limited to twelve meals weekly, or who keeps to this program, eating moderately, but who never feels satisfied. Such a person might do better on a semi-monthly fast of thirty-six hours, and alternating between two and three meals daily. Experimentation may be necessary to help the individual to determine his or her own requirements and capacities, which may be influenced by the rate and efficiency of the metabolism and assimilation.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 14. History

## 14. History

Dr. Shelton (*Volume II*, pp. 274-276) quotes numerous students of history as saying that the Greeks and the Romans, for more than a thousand years, ate one meal a day—and their armies marched for days "under loads of iron, clothes, and provisions that would stagger a modern porter."

During the zenith period of Grecian and Roman civilization, the firmly established rule was that a health-loving man should content himself with one meal a day, and never eat until he had leisure to digest, i.e., not till the day's work was wholly done.

Dr. Felix Oswald says, "The evening repast was a kind of domestic festival, the reward of the day's toil, an enjoyment which rich and poor refrained from marring by premature gratifications of their appetites."

After the Greeks and Romans acquired power and riches, their sensuous indulgence in food was

followed by their physical, mental, and moral decline.

The Persians ate one meal daily. The Jews from Moses to Jesus ate but one meal a day. They sometimes added a lunch of fruit. For more than a thousand years, the one-meal-a-day plan was the established rule among the civilized nations inhabiting the coast lands of the Mediterranean.

Even today, primitive tribes eat their daily meal after the hunters return—if the hunt fails, they have no meal.

The two-meal-a-day plan survived in England at least until 1858. With its increasing prosperity, England adopted the three-meal-a-day program.

When Sylvester Graham (early Hygienic pioneer) began his career as a temperance lecturer in the United States, gormandizing was one of the favorite indoor sports. It was not unusual to serve as many as thirty or more kinds of meat and fish at a ceremonial banquet. Gentlemen sometimes sat at the table for as long as seven hours for one meal—followed by gout and other penalties of overrating.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 15. Today

## 15. Today

Though most people still overeat today—there has been some improvement in the last 150 years—but not nearly enough. Look around you—how many people have maintained their slender figures through the years? Thousands of people are significantly, even grossly, overweight.

The prevalence of diet fanaticism (and sometimes fasting fanaticism) is perhaps even more dangerous than the overeating/overweight syndrome.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 16. Fasting Fanaticism Vs. Rational Fasting

## 16. Fasting Fanaticism Vs. Rational Fasting

Most people are fearful of fasting, calling it a "starvation" diet, and are convinced they could never fast. At the opposite pole are those who become fanatically addicted to fasting, either because they believe it will control their weight, or that it will improve their health.

These people don't really understand fasting at all. Fasting may, in general, be divided into three categories:

1. Therapeutic Fasting—Ten to thirty days, or longer, for relief of a pathological problem (or for weight reduction, in some cases)—in general, to be undertaken not more than once a year (if fifteen to thirty days or more), or twice yearly (if ten to fourteen days). Such fasts should be supervised. Some people believe that ten-to-fourteen-day fasts twice yearly are beneficial for almost everyone. Others believe such fasts should not be undertaken without reason. This is my opinion.
2. Maintenance Fasts—For general health improvement, or for further progress between therapeutic fasts (three to five days, not more than once monthly, or perhaps bimonthly, in some cases).

Might be useful for weight control for some people. Fasting for three days a month, without a reason, is really not advisable or necessary. If one is not experiencing any problem, there is no need to fast.

3. Weekly or biweekly 36-hour fasts, as part of the regular program—a good idea for most people. I really do not regard this as fasting—more like a respite for the digestive system.

Dr. Vetrano (*Dr. Shelton's Hygienic Review*, November 1979, p. 79) says, "For maximum health, one does not have to fast unless injured or unless there is an acute crisis of some sort. If you live genuinely Hygienically, all you need, because of a polluted environment, is a once-a-year rest and tune-up fast of about eight to fourteen days. If you live in the country, away from all types of pollution, you may not require a fast of that length.

"Fasting one day a week may be too much for some people. They may not be able to gain weight, or muscle, by fasting this often. Fasting three days a month, for no reason at all, is not necessary. When your hunger is absent, fast. As long as hunger is present, and there is no physical or mental problem, then there is no reason to fast. Just live Hygienically."

Fasting fanatics sometimes fast every other day, or take a two- or three-day fast every week. They sometimes fast for longer periods—thirty or sixty days or more—when there is no therapeutic reason for doing so. They may fast a week or more at frequent intervals—every month or so (or oftener).

Some of these people embark on this type of fasting "program" in the hope that frequent fasting periods will gradually result in rejuvenation and optimal health (or in an effort to normalize their weight). They do this in the mistaken belief that such erratic fasting can achieve the same dramatic results as a prolonged fast.

*Such capricious use of fasting may prove to be dangerous. Short fasts, taken at too frequent intervals, produce enervation and exhaustion, and create nutritional deficiencies.* Serious problems cannot be corrected in this manner.

To a certain limited extent, well-planned, well-spaced short fasting periods do have a health-improvement potential, but, even in those cases where successful remission of a serious problem is achieved in this manner, it is infinitely slower than a supervised, prolonged fast, and not nearly as certain.

Much of the rejuvenating and therapeutic value of a prolonged fast (fourteen to thirty days, or longer) on distilled water only, may be attributed to the *uninterrupted*, orderly succession of phenomena initiated by the organism when continuously deprived of external food sources.

As the fast progresses, elimination of toxins is accelerated, and the body continues to explore its reserves for life-sustaining materials. Nutritional elements which have been stored in the body are released into the bloodstream, to be salvaged and absorbed by the cells. As the fast progresses, the utilization of available supplies is accomplished with increasing economy and efficiency.

Ideal conditions for maximum debris autolysis and healing are produced by *prolonged* abstinence from food, and there is a steady weight loss.

By contrast, *erratic, frequent, short fasting* periods are a drain on the organism, without a corresponding recompense. For each fasting period, the body must undergo the stresses of adapting to the fasting situation and readapting to the eating situation, with very little time in between to experience any benefits.

If you are trying to lose weight, this is a poor method, and apt to not only be unsuccessful, but also to be a threat to your health. You may lose a few pounds when you fast and gain it back between fasts—which is worse than not losing the weight at all. Such a practice will not only be self-defeating, but will result in weakness and malnutrition—even if you are overweight.

Utilizing planned, well-spaced fasting periods of from ten to thirty days is the easiest, quickest and most

effective way to lose weight—for many people. Pounds quickly melt away, with a bonus of health improvement. In this type of fasting, the readjustment to eating is quite different than the constant seesawing between eating and fasting, which usually leads to gorging on the days you are eating.

After the weekly thirty-six hour fast, one has a keen appetite, but, as a rule, there is no tendency to overeat in order to compensate for the lost meals.

Even a monthly (or bimonthly) three-day fast is not usually followed by an uncontrollable desire to "eat everything in sight."

Fasting ten to fourteen days twice a year, or thirty days once a year (if there is a therapeutic necessity for a thirty-day fast) is followed by a readjustment period, but, ordinarily, this infrequent situation does not lead to habitual overeating. In fact, in many instances, such prolonged fasting periods (*under professional supervision, of course*) seem to reduce eating capacity and cravings for frequent large meals and unwholesome foods.

Even those people whose prolonged fast results in an increased appetite will find the annual or semiannual readjustment to a moderate eating program manageable, even though some thought control will be necessary to "get over the hump."

But people who are always "recovering from" the previous fast at the same time that they are within a few days of entering another fast are almost helpless to control the overeating and even bringing urges, since such compulsions are created by the body's demands for more and more food to counteract the nutritional deficiencies produced by the unwise use of fasting as a modality to replace moderate and healthful eating and living habits on a daily basis.

Each time one fasts, vitamins and minerals are lost, and an expenditure of energy and a loss of reserves are experienced. These might be weighed against the anticipated beneficial effects of the fasting period.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 17. Special Problems

## 17. Special Problems

Some people cannot use fasting at all (of any type, frequently, or lengthy) as a tool for weight control, because all it does is to cause them to seesaw between "starving" and "gorging." This is, sadly, especially true of many grossly obese people. This may be because their metabolism is abnormal, because the problem is glandular or congenital in origin, or because of any of several other possible and complicated factors.

Many authorities believe that an important cause for lack of obesity control is too many fat cells. People who have been grossly obese, especially if they were fat children or teenagers, have a special problem. When there is weight gain, there is a multiplication in the number of fat cells, but when weight is lost, the number of fat cells does not decrease, the cells simply grow smaller.

The Hartbargers (*Eating for the Eighties*, pp. 155-156) say, "From the moment of conception through the first year, virtually all the organs and tissues undergo intensive growth, including cell division. During these early stages, the most elementary functions of each organ are determined. Malnutrition can have its most lasting effect on physical and mental development at this time. By the age of ten months, for example, the number of brain cells has been determined for life. There will not be another period of such rapid general growth until adolescence.

"Overnutrition, incidentally, can have effects similar, though opposite, to undernutrition. A good example is the fat cells. Too many fat cells are thought to be a major problem in obesity control (or the

lack of it). The two critical periods for fat cell growth are, predictably, early childhood and adolescence.

"Once cell division has ceased (the third stage), the effects of deficiencies and overfeeding are usually more temporary. A particular organ may be smaller or larger for a time, but an appropriate adjustment in food intake will normalize things again."

Dr. Richard Lopez of Florida International University (*St. Petersburg Independent*, September 14, 1979, Bob Rabin, Knight-Ridder Newspapers) says that those who have been overweight since childhood have a far more serious problem, because the body's fat cell production is greatest in the early years. He says, "Fat cells are very closely related to appetite. When you lose weight, you don't lose fat cells, you lose fat stored in them."

Many people with large numbers of fat cells are almost like alcoholics. They are foodaholics. Even faithful Hygienists with large numbers of fat cells may fight a continual losing battle. I know one such Hygienist who once fasted down to considerably below one-hundred pounds, but the obesity returned, inexorably, in spite of dedication and moderate eating. She continues to take twice yearly fasts, and to eat moderately, with only minimal progress. It may well be that no more can be done in such a situation, but no one should accept an impasse unless every avenue has been explored. Most situations can be improved—sometimes, all it takes is the determination to succeed, even when the odds are against you.

People who seem to be able to eat a great deal and never gain weight have faster rates of metabolism, which is probably determined by their genes. All raw food diets usually make weight control easier for most people. Addictive eaters may still gorge on all raw foods, but it is simply not possible to eat as much food when it is in its natural form—the very bulk of it is so filling. All-day-long snackers can still become obese on raw food—one should eat no more than two or three times daily.

Actually, the only way to improve one's health, or eventually achieve normal weight, is by healthful living. The fast only expedites the process, especially in its initial phases.

In those cases of obesity where fasting seems only to complicate the problem, the solution lies in motivation, mind control, and strict, uncompromising planning of an eating program that will produce a slight, gradual, but steady weight loss.

This usually requires a powerful incentive and complete commitment. It also requires a vocation, avocation, or pursuit that will effectively fill the days with the most interesting and enjoyable means of satisfying one's need for feeling productive and useful, and thus improving one's self-image.

It is a great idea to become involved in some cause, to commit one's self to a few deadlines which must be met, and thus end the preoccupation with food as life's best reward.

Regular, adequate and vigorous exercise is of the utmost importance, whether one is seeking improved health or a new figure. And all the other principles of Hygienic living, which we have repeatedly enumerated and emphasized, must be part of the daily program of living.

Fasting fanaticism is never successful in the long run. It may even produce pathological anorexia—loss of appetite, or inability to eat.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 18. Diet Fanaticism

## **18. Diet Fanaticism**

Diet fanaticism may also produce anorexia, or the same weight seesawing which is sometimes the result of fasting fanaticism. This has been called the "yo-yo" syndrome—lose some weight, gain it back—down-up—up-down. The combination of pathological and psychological problems that are thus created

can be very destructive.

Hundreds of reducing diets have been offered to the public over the years. Diet fanatics have tried them all. When reducing diets are tried and ultimately abandoned, it is frequently because they proved to be too difficult, too frustrating—or because they just didn't work. And the dieter wails, "I just don't have enough willpower!" Some of the dieters actually do slim down, some (rarely) permanently; and some temporarily, often seesawing between dieting and gorging.

But the dieters seldom give any thought to whether these diets may be inconsistent with their dietary needs, perhaps even dangerous. The repeated experimentation with diets that emphasize certain foods, and prohibit other foods which are necessary to health and well-being, do much damage. The foods prescribed are chosen for their weight-loss potential, with little regard for their other effects on the body. People may wind up with bodies that are unable to respond normally to the food that is taken, and unable to utilize necessary food elements.

### **18.1 The Only Safe and Correct Diets**

The only correct diet for regular use is one that meets all the nutritional needs of the body in a rational manner, without threat or stress. The Hygienic food program does just that.

*The only safe temporary therapeutic (or weight-loss) diets—other than correctly utilized total fasting periods—are the Hygienic elimination diets.* Elimination diets are diets low in proteins and other concentrated foods, which cause the organism to accelerate the autolysis of toxins and fats (but never as efficiently as fasting on distilled water only).

### **18.2 Seventy Million Overweight Americans**

Frost and Sullivan, Inc., a national market research company, noted that seventy million overweight Americans are willing to do almost anything to shed some weight; they use appetite suppressants, obesity prescriptions, reducing pills, diet books, mechanical devices, health spas and even surgery such as intestinal bypass operations, cutting of the vagus nerve, and gastric stapling.

### **18.3 High-Protein Diets**

Many popular diets emphasize high protein. The high-protein diet may have a disastrous potential when utilized for long periods of time, whether used after a diagnosis of hypoglycemia (low blood sugar), or whether it is used in the mistaken belief that it is the best road to weight reduction or improved health.

The rationale of high-protein diets for weight loss is based on the fact that protein requires much more body energy for digestion and metabolism than it supplies. The danger lies in the fact that the end products of large amounts of protein, particularly flesh proteins, will result in degeneration of body tissues, producing liver, kidney and digestive disorders, as well as gout, arthritis, and other degenerative diseases.

Dr. Ralph Bircher-Benner, in an article in the September 1975 *Hygienic Review*, confirms these and other inevitable consequences of the overconsumption of protein, including hyperacidity, osteoporosis, dangerously high phenylalanine and tyrosine content in the blood, poor protein metabolism and irritation caused by uric acid. (Phenylalanine and tyrosine are amino acids, two of the building blocks of protein, excessive amounts of which are formed when protein is decomposed, as by putrefaction.)

Dr. Alec Burton, the brilliant Australian Hygienic doctor, says that the high-protein diet of seventy-five to one-hundred grams daily (or more) is beyond anyone's needs—or capacity to process without toxicity.

When protein is consumed in greater amounts than can be processed efficiently, the number of highly-toxic nitrogenous compounds are released. One such compound is ammonia; another is kinotoxin,

which, accumulating in the muscles, impairs working capacity and causes fatigue. In addition, high protein consumption results in excessive carbon and sulfur in the blood, which also causes complicated problems. Acid end products of protein, such as urea, uric acid, adenine, etc., beyond a certain normal range, cause tissue damage, degeneration and destruction.

Dr. Gerald Benesh says, "A study of physiology shows that all excessive and unnecessary protein is processed by the liver. It subsequently goes through numerous biochemical changes until it is finally excreted as ammonia and other end products of protein metabolism via the kidneys. This excessive load and additional biological function leads to enervation and eventually the breakdown of these vital organs.

"The liver has to cope with the heavy load of uric acid and urea which has to be buffered (neutralized) at the expense of the alkaline salts, leading to an unbalanced body chemistry and disordered cell and body function. This continued abuse, in time, leads to serious pathological conditions. Nephritis (inflammation of the kidneys) has been reported to result from a very high intake of animal protein." ("The Protein Question")

Research by Professor Uri Nikolayev of the prestigious Psychiatric Institute in Moscow has confirmed links between mental disturbances and protein derivatives, and studies at the Institute for Cancer Research demonstrate links between high-protein intake and cancer.

Dr. David J. Scott, of Cleveland, and Dr. Robert R. Gross, of Hyde Park, New York, who, among others, have researched this subject extensively, are convinced that the individual who resorts to high-protein diets for weight loss may wreck his health in the process.

## **18.4 What A High-Protein Diet Can Do**

I know a lady, a registered nurse, who was on a high-protein diet for twenty-two months (including massive amounts of food supplements), after a diagnosis of hypoglycemia. She steadily grew worse on the high-protein diet, and developed more and more symptoms. She visited hospital emergency rooms, in severe pain, three times. Her intestinal tract was packed with feces and she was given repeated agonizing enemas. Her body and breath odor were unbearable.

From 1974 to 1976, her weight increased from 125 to 162 pounds. Her personality and mentality had deteriorated so much she was unable to think or make decisions or drive a car. She had been treated by many doctors, including those in the hospitals where she worked, and the emergency room doctors, but only one of them suggested she was taking too much protein.

One, of the doctors, a D.O. who was a specialist in nutrition and hypoglycemia, prescribed the following diet and supplements (high protein, no fruit):

7 a.m. 8 oz. milk with protein powder and brewer's yeast

8 a.m. 2 eggs, 1 slice toast, glass chocolate milk

10 a.m. glass milk with protein powder

Noon meat or fish with salad and vegetable

2 p.m. Milk with protein powder

5 p.m. meat or fish, salad, vegetable

8 p.m. milk with protein powder

10 p.m. milk with protein powder

plus B complex, 75 mg. 3 times daily

Vit. C., 1000mg 3 times daily

Vit. E, 400 units once daily

Dolomite, 2 tablets daily

All these were taken with more milk—she drank a gallon of milk daily.

By the end of March 1976, she realized that she had reached an impasse—a dead end. She remembered

she had read some books about Natural Hygiene in June 1973, but didn't believe what she read. But now, in desperation, she got them out and re-read them. They were *Fasting Can Save Your Life* and *Superior Nutrition* by Dr. Herbert M. Shelton and *The Mucusless Diet Healing System* by Arnold Ehret.

On April 1, 1976, she dumped all of the supplements and changed her regimen to a breakfast of fruit, a lunch of vegetables and a starch, and a supper of vegetables and a protein.

She went through six weeks of elimination and agony, but she did not give up. Then her energy started slowly to return. Her weight was down to 136 pounds. She was close to death at some points, but she made it back.

In the years since then, she has been able to function quite normally, though it is obvious that some irreversible damage was done by the twenty-two months of stuffing with protein and supplements.

She has been a dedicated Natural Hygienist since then, and has been reluctant to function in her profession as a registered nurse, since she no longer believes in the type of treatment she would be required to assist in implementing.

## 18.5 Low-Carbohydrate Diets

The "low-carbohydrate diet" is another name for a high-protein diet. Dr. Jean Mayer's (and Jeanne Goldberg's, R.D.) column, "Food for Thought," (*St. Petersburg Times*, June 24, 1982) says this diet is described as "historical," having been created more than 100 years ago by Dr. William Harvey, a British ear surgeon. The diet was immortalized by his patient, William Banting, who was delighted with his weight loss and wrote a best-seller, *Letter on Corpulence, Addressed to the Public*, in 1864.

Dr. Mayer (et al.) says, "Eventually it faded into obscurity, but the diet resurfaced around the turn of the century when the Earl of Salisbury's doctor used it to treat the Earl's weight problem. The basis of that diet was a big patty of chopped beef. It is, in fact, from this that Salisbury steak got its name.

"The low-carbohydrate diet resurfaced a third time in 1953, as the Dupont Diet, and has been with us continuously in literally countless variations since then. While it appears to be true that some people temporarily control their appetite—and thus lose weight—such diets are undesirable in the long run because they are generally higher in fat and may create a predisposition to high blood cholesterol and diseases of the heart and blood vessels."

## 18.6 The Atkins and Stillman Diets

The Stillman Diet (*Dr. Stillman's 14-Day Shape-Up Program*) and the Atkins Diet (*Dr. Atkins' Diet Revolution*) are variations of the high-protein, low-carbohydrate diets. Dr. Atkins advises using fats like heavy cream, butter, oils, etc. He calls his diet the "High-Fat, No-Carbohydrate Diet," though a very small amount of carbohydrates are permitted. Dr. Stillman, on the other hand, says the "high-fat" idea is all wrong, and calls his diet "High-Protein, Low-Fat, Low-Carbohydrate Combination."

Dr. Atkins recommends that "everyone should take vitamin and mineral supplements," and Dr. Stillman advocates the use of vitamin and mineral supplements "in optimum dosages."

Dr. Atkins' book has two paragraphs on exercise, one for hypoglycemics and one for "dieters who go astray." Dr. Stillman has a chapter on the benefits of exercise.

Both diets include all kinds of flesh foods and animal products, and permit condiments, coffee, tea, diet soda. Fruits are absent, and the use of vegetables is very small. Dr. Atkins says "no bread," Dr. Stillman permits "protein bread," toasted. Dr. Stillman permits alcoholic beverages, even wines in cooking.

## 18.7 The Scarsdale Diet

The Scarsdale Medical 14-Day Diet includes flesh foods, low-fat cheese, small amounts of fruit and

green vegetables, no fat, "protein bread," toasted, coffee, tea, diet soda, but no alcoholic beverages. Carrots and celery between meals, seasonings, and spices are permitted.

Dr. Scarsdale says that all the vitamins and minerals needed daily are found in the foods in the Scarsdale Medical Diet; and gives a list of the vitamins and minerals and the foods in which they are found.

Dr. Scarsdale recommends brisk walking at least two miles daily, as well as swimming, tennis or other sports.

The Scarsdale Diet is essentially a high-protein, low-carbohydrate diet.

## **18.8 The Beverly Hills Diet**

The Beverly Hills Medical Diet (Lose Ten Pounds in Fourteen Days) uses flesh foods, but it is recommended that not more than four ounces of meat daily be used; also the use of less red meat and more poultry and fish is advocated, as well as the use of one ounce daily of fresh raw nuts and seeds. Nonfat dairy products and egg white are recommended. Wholegrains and legumes are also used.

The diet also includes generous amounts of fresh vegetables and moderate amounts of fresh fruits. The use of "complex carbohydrates" is recommended (unrefined carbohydrate foods). It is "thumbs down on all unnecessary fats (any kind)" and salt, sugar, and processed foods are to be omitted, as well. Spices are permitted, but not coffee, alcohol or tobacco.

The diet calls for high-vegetable, low-fat meals. Lemon juice or vinegar are to be used as salad dressing, and as many foods as possible are to be eaten raw. This diet permits "eating-all-the-time on permissible foods. Eat all day long and eat in between meals and when hungry from the special list of the raw complex carbohydrates. Carry them with you all day (raw vegetables)."

Dr. Stillman criticizes Dr. Atkins' high-fat diet, and Dr. Arnold Fox (Beverly Hills Diet) criticizes the Atkins and Scarsdale diets. Each believes his is the miracle diet.

Dr. Fox says that the low-carbohydrate, high-protein diet causes bodily harm, such as calcium depletion, dehydration, sleeplessness, nausea, fatigue, atherosclerosis, gout, hypoglycemia, vascular, thrombosis, liver and gall bladder diseases, hypertension, cancer of the colon and breast, cardiac arrhythmia, postural hypotension and coronary heart disease, and says he does "mean to scare you."

The Beverly Hills diet is better than the high-protein, low-carbohydrate diets criticized by Dr. Fox, principally because it advocates the use of large amounts of raw fresh vegetables, and allows moderate amounts of raw fresh fruit. But the all-day-long eating plan (no rest for the digestive system) can result in a lot of damage if continued for long periods. And the generous use of dairy products and egg white, the use of vinegar and spices, and the daily use of flesh foods, will also eventually cause problems.

Dr. Fox recommends "wogging" for exercises—walk a bit, jog a bit, a minimum of thirty minutes, four days a week, and advocates the use of vitamin and mineral supplements.

## **18.9 The Pritikin Diet**

This diet includes two kinds of whole grain foods daily, bran, beans, peas, potatoes, sweet potatoes, and a variety of vegetables and fruits. For vitamin B-12 it calls for six ounces of low-fat animal protein per week (or unwashed, unpolluted produce) or vitamin B-12 supplements. In addition to three full meals daily, the diet provides for snacking between meals: "Don't go hungry between meals." Spices are permitted, but not coffee, alcohol, or tobacco.

This is a vegetarian (or almost vegetarian) diet, but the good "track record" of the Pritikin Program is due more to the excellent exercise program than to the diet. Hygienists, of course, find the preoccupation with vitamin B-12 unnecessary, and find the frequent snacking inadvisable, giving the digestive system inadequate time to process the previous meal before ingesting more food.

## 18.10 Weight-Watchers

The popular Weight-Watchers Diet is essentially a low-carbohydrate, high-protein diet, which has been more or less successful, due to a great extent to its methodology—group supportiveness, public approval for accomplishment, and public disapproval for backsliders. Techniques for changing habits and self-control are also provided.

Liver, steak, veal, pork, turkey, chicken, frankfurters, fish, shrimp, salmon, tuna, sardines, eggs, and cheese are used for protein. They say "buy meat as lean as possible" and allow ten to twelve ounces of meat, fish, cheese, and eggs daily (a little more for men).

Three full meals and two snacks are permitted. A choice of cereal, bread, or potatoes is offered at meals. Two pieces of fruit daily are allowed, as well as generous amounts of nonstarchy vegetables.

They recommend using as little coffee and tea as possible, especially if it disturbs sleep, and consider the use of alcohol inadvisable. Nothing is said about seasonings, except for the role of salt in the retention of fluids in the body.

"Increased activity" is advocated, and emphasis is accorded the fact that the value of exercise "goes far beyond its impact on weight—improving the health of the heart and circulatory system, the general health, and the state of mind."

## 18.11 The Last Chance Diet

I am not sure whether the Last Chance Diet should be considered as "Fasting Fanaticism" or "Diet Fanaticism." Though it was not a true fast, the participants really received no food.

The only "food" ingested was a so-called "predigested liquid-protein formula" (a dark, syrupy liquid made from uncured cowhide, beef tendon, and artificial flavoring) which was said to contain all the amino acids (the building blocks of protein), no carbohydrates or fats, and very few calories. Vitamin pills, coffee, tea, and diet soda were also used, as well as drugs, depending upon the doctor's discretion.

In 1977, this "diet" was highly touted in the press and on television as a revolutionary, effective, safe way to deal with obesity. Individuals on this diet received no solid food for the duration (up to nine months), usually under the supervision of a medical doctor (although the liquid was also available in health food stores).

In November of 1977, twenty-six deaths of these dieters were reported, including the death of the wife of a specialist in internal medicine, commandant of the Air Force Base Hospital near Tampa, Florida.

The author of The Last Chance Diet, Dr. Robert Linn, a forty-three-year-old osteopath (whose diet book sold two million copies), convinced many people that this method of weight reduction was superior to another method which had been gaining recognition—a total fast, under qualified supervision, of usually a much shorter length of time, during which nothing but water is ingested—a Hygienic fast.

A Hygienic fast relies on the body's own indications that reserves are becoming depleted, so that the fast is terminated long before approaching any danger point.

Long before we began to get reports of deaths of people on "The Last Chance Diet," I alerted people to its dangers. Since, under the Last Chance Diet, the body is always receiving liquid protein, stimulants and medication, how can it ever be able to alert one with reliable signals that it has reached the time to call a halt?

Advocates of the Last Chance Diet still deny there is any proof that their product, "predigested liquid protein," caused the deaths. Dr. William H. Foege, director of the Center for Disease Control at Atlanta, Georgia, made a concentrated investigation of the cases of fifteen women on this diet who died suddenly of heart-related causes.

Each of the deaths was sudden and involved a person using a liquid-protein diet exclusively for a long

period of time.

The deaths were attributed to ventricular fibrillation, in which the heart beats wildly and does not pump blood, but the cause of the irregular heartbeat is unknown. Dr. Foege said the fifteen women had dieted for an average of five months and had lost an average of eighty-three pounds. Twelve of the fifteen were under medical supervision. Foege concluded "there is a definite risk in using the product." (From a United Press International dispatch, *St. Petersburg Times*, January 5, 1978.)

Actually, it is not necessarily only the product, per se, that should be suspect, but the methodology as well.

## 18.12 Starch Blockers

What about the "new and revolutionary" starch blocker tablets that "have swept the country in recent months," according to a news article? (*St. Petersburg Times*, Jane Brody, p. 1A, July 2, 1982.)

The ballyhoo claimed that doctors had confirmed that they are perfectly safe. One can eat high-caloried starch foods without paying the price in weight gain, because the starch blockers act to prevent digestion and assimilation of the starch, which passes through the digestive tract relatively unchanged, much as does fiber or roughage.

It sounded plausible, but even though I had no means of disproving these claims, I would not dream of recommending such a product. I knew that, ultimately, it would be discovered that such unnatural interference with digestive processes would exact a price. It seemed to me that—since large amounts of roughage, such as are found in bran, inhibit absorption of minerals—this would very likely be true of starch which is eaten and not absorbed, but disposed of as unusable. And, I thought, "who knows what additional side-effects or problems would eventually be discovered?" A few days after I wrote the above comments about the starch stopper tablets, I heard on a newsbreak (at 9 pm on WEDU, Channel 3, Tampa, Florida, July 1, 1982) that the F.D.A. had announced that the starch blockers are untested and probably unsafe, and ordered them off the market. Some complaints of nausea, vomiting, diarrhea, and stomach pains after their use had surfaced. The F.D.A. was also investigating five emergency room hospitalizations that had been linked to the use of starch blockers.

As of two days later (July 3, 1982) the starch blockers were still being offered on TV, and the TV evening news said "they're selling like hot cakes." In the *St. Petersburg Times*, July 5, 1982, the American Medical Clinics, Inc., with branches in St. Petersburg, Seminole, Holiday, and Hudson (Florida), advertised, "Join now and receive one week free plus twenty-five free starch blockers—lose up to a pound a day. We're the proven, professional weight-loss method."

Jane Brody says, "The starch blockers are extracts of raw beans, usually kidney beans. They are said to contain a substance that inhibits the enzyme amylase which digests starch in the body. Consumers are told to take a certain number of tablets before eating starch-laden foods, such as bread, potatoes, pasta, rice, and beans. The pills are marketed under many different brand names and prices range from five dollars to twenty dollars for fifty tablets. By one estimate, in the course of a week, Americans are now swallowing more than ten million such tablets. Nutrition experts have reported that if the tablets work as described, they would result in large amounts of undigested starch reaching the large intestine. Intestinal bacteria could then digest the starch and produce flatulence, abdominal cramps, and diarrhea.

Manufacturers have been marketing starch blockers without federal approval under the presumption that, as an extract of beans, they were a food, not a drug. However, the drug agency said that, regardless of their source, starch blockers 'may affect the body's normal metabolic functions' and thus have drug-like effects."

A substance is classified as a drug if it is used for a nonfood purpose, and if it alters a body function. The manufacturers have refused specific information about the exact composition of the product, and no adequate effectiveness or safety data have been supplied.

### **18.13 Sucrose Polyester**

July 15, 1982—The evening news reported another "breakthrough" (WFLA-TV, Tampa, 6:30 and WTVT-TV, Tampa, 7:00). "Sucrose polyester" is a fake fat that looks, tastes, and smells like vegetable fat. It can be used as a spread for bread, or for cooking, or for any purpose for which butter or vegetable fat might be used. It was said that one could save 500-600 calories daily by using it. No one said exactly what is in sucrose polyester, but it was described as a synthetic substance.

It is to be treated as a prescription drug, subject to approval by the F.D.A. Procter and Gamble holds the patent on the fake fat, and they expect to market the substance as soon as it is approved by the F.D.A.

Another miracle! (But don't count on it!)

### **18.14 The Golden Door**

The Golden Door, a fabulously expensive health spa in California, uses a 579-calorie, one-day liquid diet, which they say can help take off some extra weight while refreshing the body and mind. It is used principally to start off a diet week. They warn: this liquid diet should not be followed for more than one day, and it is advisable to see your doctor before following this one-day diet or any other liquid "fast" or reducing program.

The ingredients of the liquid sound fine: fruits, vegetables, and nuts. But they are poorly combined; e.g. nuts are liquified with banana, vanilla, and nutmeg; pineapple is combined with cucumber and parsley; and raw onion is used in a vegetable combination drink. Four of the drinks are supplemented with one-third ounce of sunflower seeds and three or four pine nuts.

I seriously doubt whether this one-day liquid diet would produce any significant weight loss or other beneficial result. In any event, a better choice for a one-day preparation for a diet would be a thirty-six hour fast, or a day on whole fruit only, or a day on one kind of freshly-squeezed fruit juice.

### **18.15 Plastic Coating**

A recent issue of *Healthful Living* (June 1982) described a new diet drink which performs its miracles by plastic coating the digestive tract to block absorption of food, believe it or not! It contains flavored fluorocarbons, which are the synthetic substances that give paints and plastics their coating power. The inventor believes the F.D.A. will give its approval.

### **18.16 Cambridge Diet**

A question to Ann Landers (*St. Petersburg Times*, June 26, 1982) about the Cambridge Liquid Diet, on which an overweight girl was losing a pound a day, elicited the following response: "I do not know what the Cambridge Liquid Diet is....I know of several liquid diets that have caused a great many problems—such as serious skin rashes, fainting spells, respiratory trouble and the loss of hair and fingernails."

By contrast, supervised fasting, even for long periods, results in strengthening and hardening of the fingernails. This is due to the wisdom of the body when external supplies are temporarily unavailable, producing increased efficiency in the distribution of available nutrients. More details of this interesting phenomenon, and many others, will be provided in the lessons about fasting.

### **18.17 Staple In the Ear**

Another relatively new weight-loss system is the staple in the ear, which some claim is successful and others have found useless. What are the side-effects and negative results likely to be—as a result of blocking natural stimuli?

## 18.18 Appetite Suppressants

All kinds of appetite suppressants are offered: Ayds candy, Dexatrim pills, Figurines bars, prescription drugs, etc. Needless to say, they are all harmful drugs.

## 18.19 How Ridiculous Can You Get?

I have not discussed some of the more ridiculous diets, like the egg diet (eating nothing but eggs for a week or so): skim milk and bananas; steak and eggs and tomatoes; cabbage soup and rice; the grapefruit diet; eating a half grapefruit before every meal "because it will reduce the weight-gain potential of other foods;" the high-calorie, weight-loss diet; the protein-sparing modified fast: eat nothing but about nine to ten ounces of meat or fish per day, plus supplements, coffee, tea, and diet soda; eat all you want of one or two foods.

Most of these have one thing in common, they reduce calories in a gimmicky way, and one learns it is possible to lose ten pounds in two weeks eating almost any crazy combination of foods, as long as calories are drastically reduced. But what happens afterwards? Back to the old yoyo syndrome!

## 18.20 I Have Made My Point

It would be a losing battle to try to research and describe all of the diets and weight-loss modalities which crowd the marketplace and compete for the dollars of the gullible. Although I have merely "scratched the surface," I believe I have made my point.

Magic formulae all eventually turn out to be wolves in sheep's clothing, but rational living and intelligent diet planning, working with nature, instead of trying to outwit her, never become obsolete.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 19. Bulimia

## 19. Bulimia

One pernicious result of diet fanaticism is a binge-and-purge eating disorder, called bulimia or bulimorexia (obsession with eating, but with a compulsion to be thin). It may start after a period of stringent dieting, subsequently degenerating into alternate dieting and binging. The person may eat up to 40,000 calories (or even more) in a couple of hours.

One lady described a typical binge: a couple of Burger Queen, burgers with French fries; then a repeat at McDonald's; followed by a dozen doughnuts at the doughnut shop; a couple of sundaes at Dairy Queen; then home to raid the refrigerator; after which she throws up all of it.

In the earlier stages, the vomiting is self-induced, but it later becomes involuntary. Bulimics may eat and throw up ten times in one day. Some bulimics take large amounts of laxatives and/or diuretics every day to prevent weight gain, or simply to relieve pain after the binge. They may starve themselves for a couple days afterward.

Eventually, the bulimia is so uncontrollable that every time they start to eat, it turns into a binge. It controls them completely. They are no longer doing it for the enjoyment of eating, or thinking about weight control, but because they can't help themselves. It develops to a point where it is a physical addiction in addition to a psychological disorder.

It becomes very, very dangerous, and can result in metabolic alkalosis, a destruction of the body's ability to maintain its acid-alkaline balance. It can damage the liver and kidneys, and can be life-threatening. The constant eating (food in their mouths for hours at a time) also results in tooth decay.

This disorder was discussed on the Phil Donahue Show, WTSP, Channel 10, Tampa, on June 28, 1982.

Most bulimics are women, only 5% are men. Most bulimics look normal and are not significantly overweight or underweight, but food has become their total preoccupation, and they spend six to eight hours a day in its involvement. A bulimic usually binges and purges in secret, and they have been said to spend as much as several hundred dollars on food in one weekend.

This behavior is epidemic in colleges; up to 30% of college students practice some form of bulimia, according to the 20/20 TV program on July 1, 1982.

It is also common among dancers and actresses (very few men are bulimics). Actress Jane Fonda admitted to having been a bulimic for years. She said the more you do it, the more you need to do it. She said as she grew older and realized what she was doing to herself, she was determined to stop. It took her sixteen years to break the pattern. She accomplished it by the use of willpower and exercise.

Both anorexia and bulimia are severe and dangerous eating disorders.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 20. A Rational System Of Weight Control

## **20. A Rational System Of Weight Control**

Most of the people who are concerned about their weight need not necessarily fast, nor should they use any of the legion of "reducing diets" or "systems" that are offered from all sides.

For most people, the Hygienic diet itself is a rational system of weight control. It provides complete and optimal nutrition, with the least expenditure or waste of bodily energy—and without the surfeit or redundancy that gluts the organism and produces obesity and disease.

When a nutritionally-superior diet is maintained, the weight of the body tends to normalize. There is built-in weight control in a food program which includes a large percentage of fresh, whole, uncooked vegetables and fruits; Such a vitamin- and mineral-rich, high-residue, fibrous diet is not nearly as conducive to overeating as the conventional diets.

It may be worthy of note that, of the various programs which have been offered to the public, those which have been either harmless or least harmful, and have "enjoyed" even a modicum of success are those which include fresh fruits, fresh vegetables, and exercise in the regimen, and thus begin to approach the Hygienic system.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 20. Heroic Methods For Compulsive Eaters

## **20. Heroic Methods For Compulsive Eaters**

In view of the pitfalls encountered by compulsive eaters who manage to overeat and gain weight even on such a superior food program, heroic methods must be devised to help them. It is hoped that the suggestions outlined in this lesson will prove successful.

This lesson contains an excellent article by Dr. Bass, giving specific ideas for developing willpower,

mind control, and new habits.

## 20.1 Surgery for Obesity

Overeaters can be saved from suffering and disease. The misguided individuals who resort to cutting the vagus nerve, intestinal bypass surgery, or gastric stapling because they believe the Hygienic system and self-discipline are too difficult, will have a rude awakening. Their "easy way out" will prove to be their complete undoing.

In addition to the obvious insult to the organism by the surgery (and these are major abdominal surgical procedures), the side effects and problems that usually follow are even worse. And to add further "insult to injury"—these procedures are often no more "successful" than other "panaceas" for weight control.

"Many experts now feel that operations for obesity (such as intestinal bypass surgery) are not worth doing, because of the side effects and problems that usually ensue. A recent review by the Ottawa (Canada) School of Medicine suggests that the failure rate for gastric stapling may approach 50%. Furthermore, early results can sometimes be misleading. While there may be a sudden and dramatic initial weight loss, many patients find ways of regaining the lost weight, even though the stomach capacity has been reduced. In short, gastric stapling is still regarded by many as 'experimental'—at least until we obtain more long-term follow-up data on its effectiveness and possible side effects." (G. Timothy Johnson, M.D., "House Call," *Suncoast News*, 1/6/82.)

## 20.2 Overeaters Anonymous

So we are back to controlling the body by learning control of the mind. The easy ways out are dangerous myths. Those who are determined to succeed *will* succeed. They *must* succeed. The alternatives are too grim to contemplate.

"Overeaters Anonymous" has helped many people. Those who can't make it on their own should enlist their help. Be sure to read the inspirational article in this lesson entitled "Help—I Can't Stop Eating." The author is now a "truly high-quality vegetarian"—a vegan—and says in part: "Because we have come to believe that most of the fat is between our ears, the (Overeaters Anonymous) program works to help change our thinking, so that we no longer want to overeat. That's the beauty of it; it's the miracle every compulsive eater has long dreamed of, to eat all he/she wants and maintain a normal weight. It is only possible when all you truly desire is a normal amount of food."

The article tells how to reach a group nearby, or, for those in isolated areas, the same things can be accomplished by "loner kits" and mail sponsors.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > 22. Knowledge And Wisdom

## 22. Knowledge And Wisdom

Overeating, fasting fanaticism, and diet fanaticism have physical and physiological overtones, but they can be controlled in the mind. The first and best tool is knowledge.

Dr. Keki Sidhwa says, "The study of Natural Hygiene may be viewed as a journey—a journey from knowledge to wisdom." He says that when you apply Natural Hygiene to your life, health and wholesomeness emerge, though it may take time. Ultimately, the supreme experience of wisdom comes to possess us, transforming us, so we may, in our turn, transform the world.

## 22. Epilogue

It is generally believed that, as long as an individual is in health, or apparently so, he is not injured by habitually eating more than is really necessary for the healthy nourishment of his body, but this opinion is utterly and dangerously false. It is, indeed, one of the most mischievous errors entertained by the human mind. For there is nothing in nature more true, more certain, than these propositions: that all vital action is necessarily attended with some expenditure of vital power, and draws something from the ultimate fund of life; and therefore all excessive vital action, all intensity of vital action, increases the expenditure of vital power, and necessarily abbreviates the duration of human life; and consequently, however long the vital economy of any human body may be able to preserve the general balance of action, between the composing and decomposing elements, and maintain a general health of the system under excessive alimentation, yet nothing is more certain than that, just in proportion as the alimentation has exceeded the real healthy wants of the vital economy, and thus caused an unnecessary Expenditure of vital power, life has been abbreviated—even though the individual dies from what is called old age, without a single violent symptom of disease. The error of opinion on this subject is common and mischievous; and the truth should be presented in its strongest light.

But we have as yet only presented the subject and contemplated it in its most favourable aspect. The case I have presented is a very extraordinary one. As a matter of fact, very few indeed who have constantly overnourished their bodies do die from old age, but as a rule they die from painful and exhausting diseases long before that period is reached. Millions of human beings perish by disease, in all periods of life, from excessive alimentation or overeating. Generally, they are cut off by disease long before they have lived out their lives, and often prematurely. And the chief cause of all such death is, I must insist, overeating.

This can readily be proved...Overeating is the chief cause of all diseases; and disease shortens and destroys life. Of that there can be no question. But even if no adventitious cause comes in to induce sudden and violent death, either local or general, the continued overworking of the system will almost inevitably exhaust, debilitate, and relax some particular organ, and so destroy the balance of action in the vital economy, and thus gradually lead to chronic disease. Adipose tissue is deposited in various parts of the body—causing ruptures of the heart and the blood vessels, and hence premature death.

It is therefore true, beyond all question, that in all countries where human aliment is abundant and easily procured, gluttony or excessive alimentation is decidedly the greatest source of disease and suffering and premature death known to man.

—Hereward Carrington, *The Natural Food of Man*, pp. 266-268

## 23. Questions & Answers

**If we are to eat only when truly hungry, and should not eat late in the evening, how do we resolve a conflict between these two principles?**

The principle preoccupation should be the correction of the habit of overeating (or of eating undesirable foods). If the day's program prevents taking meals at customary times, or if you are simply not hungry when the meals are served, and then find yourself with a compelling desire for food during the evening, it would seem best to satisfy your appetite with a fruit

meal, which may leave the stomach in a half hour or an hour, depending on the varieties eaten. I sometimes do this when I am away from home during the day, do not wish to eat the food that is available, and prefer to wait to eat my good fruit meal at home.

**Winston Churchill was a famous gourmand and cigar smoker, yet he lived past the age of 90. How do you explain this?**

The first and more important fact that determines our longevity is our heredity—our genes. Winston Churchill's long life was not due to his gormandizing and cigar smoking—it was in spite of it. If a man with such genes were to live correctly, who knows how long he could have lived?

**I would like more details about "homeostasis," so I may better understand its meaning.**

Dr. Walter B. Cannon, renowned professor of physiology at Harvard University, wrote a book (*The Wisdom of the Body*) in 1932, summarizing and demonstrating the fixity of the internal environment. In this book, he coined the word now generally used to describe the state produced by the constant adjustments made by the healthy body: *homeostasis*, derived from the Greek words that mean *staying the same*. The dictionary definition of homeostasis is "a state of physiological equilibrium produced by a balance of functions and of chemical composition within an organism." Dr. Cannon described the intricate sequences by which the healthy body regulates and integrates its functions to maintain the stability of the internal environment within narrow limits of variation. Such vital matters as oxygen, blood pressure, mineral salts, body temperature, composition of body fluids and the blood sugar level all remain relatively constant. When all the homeostatic mechanisms are functioning efficiently, every challenge to the body is handled in such a fashion as to prevent disease and permit continuous functioning.

**I have a good appetite, and I know I overeat. In fact, I usually have an uncomfortable feeling of being too full after a meal. Yet I don't gain an ounce. I would like to gain about ten pounds, as I am too thin.**

Some people can eat a lot of food and not gain weight. It is a question of the rate of metabolism. However, in your case, the very fact that you are overeating may be what is preventing weight gain. The body is unable to cope with the large quantities of food, and, as a result, much of it is not converted by the digestive system into assimilable substances. If eating more rationally (stopping before you feel so full) does not result in the desired weight gain, you might try a short fast of three days or so, or even a seven- to ten-day supervised fast (if a professional Hygienist determines this is advisable). Oftentimes the fast improves the assimilation capabilities of the body, and the individual gains weight. Also, are you exercising? An adequate, vigorous exercise program is important in improving the efficiency of the metabolism of food.

Finally, perhaps you are trying to stuff yourself in an effort to gain weight. It may be that being ten pounds below what you consider your ideal weight is what your body has determined is the best weight for you at the present time. The important question is, how do you feel? Stop stuffing yourself, and then see what happens. If you do not lose weight, and feel well, stop worrying about it. Weight is an individual matter. If you stay on a Hygienic diet, and eat rationally, sometimes the problem adjusts itself.

After my 29-day fast, it took a year for me to get up to about 95 pounds (from my fasting low weight of 68 pounds), and then I stopped gaining. I stayed on a Hygienic Program, and tried to forget about my thin appearance. I really needed ten additional pounds to look my

best. About two years later, my weight increased to around 100 pounds, for no apparent reason. Obviously, my assimilation has improved. About five years later, I experienced another five-pound weight gain to around 105 pounds, my present weight, which I have maintained for years. If I fast, I lose some weight, but it comes back to around 105 when I get back to eating regularly. Sometimes, in periods of high stress, like meeting unrealistic deadlines, or American Natural Hygiene Society Conventions, my weight drops several pounds, but gets back to about 105 when things return to normal.

**I have read that most adults need 1800 to 2500 calories (or some even more) per day to maintain their weight, and that it takes 3500 accumulated calories to gain or lose a pound. How many calories per day do you recommend?**

The effort to standardize calorie consumption is a fallacious notion. I can only say that these amounts are often much more than is needed; and the measurement of weight loss or gain in terms of 3500 calories per pound often proves to be inconsistent when put to the test. Even though many of the charts provide for differences in sex, height, size of frame, and rate of activity, there are other differences that influence food requirements. Since every person has his own rate of metabolism, efforts to standardize in terms of calories are frequently inaccurate. If one is trying to lose weight, it is useful to determine high-calorie foods, so that excessive quantities of those foods are not used. If we are discussing Hygienic eating programs only, there is usually no need to be concerned about calories. A diet of all raw or mostly raw foods would ordinarily not contain the number of calories listed in the charts as the daily requirements, unless inordinate amounts of food were taken at meals or unless the person were a habitual snacker. Hygienic eating and living produce gradual improvement in metabolism and assimilation. The initial result of changing to a Hygienic program is usually a weight loss, followed by a leveling off, which continues for varying periods of time, after which, due to improvement in assimilation, weight can be maintained on lesser quantities of food.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > Article #1: It's All In the State of Mind By Walter D. Wintle

### **Article #1: It's All In the State of Mind By Walter D. Wintle**

If you think you are beaten, you are,  
If you think that you dare not, you don't,  
If you'd like to win, but you think you can't,  
It's almost certain you won't.  
If you think you'll lose, you've lost,  
For out in the world you'll find  
Success begins with a fellow's will—  
It's all in the state of mind.

Full many a race is lost  
ere even a step is run,  
And many a coward falls  
ere even his work's begun,

Think big, and your deeds will grow;

Think small, and you'll fall behind;  
Think that you can, and you will—  
It's all in the state of mind.

If you think you are out-classed, you are;  
You've got to think high to rise;  
You've got to be sure of yourself before  
You ever can win a prize,  
Life's battles don't always go  
To the stronger or faster man;  
But soon or late the man who wins  
Is the man who thinks he can.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > Article #2: How To Make Yourself Over by Self-Programming

## **Article #2: How To Make Yourself Over by Self-Programming**

### **How to Resculpture Your Thoughts, Behavior, and Character**

The moments just before falling asleep are important to every person. They contain latent power to transform one's mental, moral and physical existence in an effective manner which, if properly utilized, may gradually alter one's external environment and one's internal character for the better. Even more important, one may use the potential power of these moments to alter his consciousness.

This exercise is done at night while lying in bed and before going to sleep. After making oneself comfortable and while lying on the back, one begins to construct scenes in which you permit yourself to become emotionally involved with your behavior on the projected screen.

To break an undesirable habit which is upsetting your life, taking compulsive overeating as an example, you begin in a manner similar to the following.

You see yourself sitting down at a table to eat a meal containing the foods you normally eat. If the table has dishes which you have found irresistible up to now, you see yourself eating the desired amount of each and then putting each dish away to go on to the next. If you want to give up the article of diet entirely, and if the food is cake or ice cream, you see yourself being offered the dish which you immediately refuse without hesitation and with strong determination. You should tell yourself that you are through with this food forever and that you even dislike it and will never desire it anymore. Feel the strong dislike and intensity of your determination as you reject these undesired articles of diet. See yourself taking another food instead which is desirable in helping you reach your goal. If you want to learn to eat a food which is good for you, but which you don't like, then feel and see yourself eating and liking it. Instead of the cake you take an apple, for example, or if you prefer, you get up from the table, tell yourself you are satisfied to end the meal here and see yourself sitting down in a comfortable chair away from the table. If you wish, visualize yourself taking a walk, or doing anything that will distract your mind from food. Try to make these scenes as vivid and realistic as though they were actually happening. The key here is to feel that you strongly desire the good act and that you strongly dislike the one you wish to give up.

The sharply-focused clearness and constant intensity of the images you produce will imprint themselves on your consciousness as you remain in this relaxed state. Choose images which are vivid and don't

allow them to become vague and dreamy. For best results, the imagination should be powerful, for here you are using imagination to make yourself over completely. This should be supported by a firm faith, secure feeling and confidence that success will follow your efforts. These suggestions should be repeated over and over with the clear visualization of success being achieved. These repetitions are to be persevered in until you reach your final goal—that of eliminating a bad habit and replacing it with a good one.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > Article #3: Say Goodbye To Compulsive Eating by Mehl McDowell, M.D.

### **Article #3: Say Goodbye To Compulsive Eating by Mehl McDowell, M.D.**

The therapeutic breakthrough came when I was searching for a clear-cut, easily definable dietary rule that would simplify weight control. I needed a rule which would be healthy, easy to live by and readily taught by behavior therapy techniques.

The rule I selected to try was the complete avoidance of all foods containing refined sugar or white flour. Using the habit-retraining techniques with which I was familiar, I programmed my willing weight control patients to dislike the sugar-flour foods and completely eliminate them from their eating style.

Now the great surprise—the breakthrough—surfaced when patient after patient came to me following several days of eating a diet free of all sugar and white flour and joyfully reported that the irresistible cravings had disappeared.

Their irresistible cravings could now be understood as the typical cravings of addicts. The mysterious urges stemmed from the cyclic, biochemical processes of addiction.

Occasionally, a patient will report irresistible cravings for some other food not in the sugar-white flour group.

But the establishment of total abstinence from the foods identified as the culprits is only the *first* phase in eliminating the addictive-like, irresistible cravings for those foods. The second phase is extinguishing the *conditioned response cravings* for those foods.

How do I eliminate these conditioned response cravings in the case of sugar-white flour addicts? I use the term "glue" and "glue" foods" to mean all foods containing any highly refined sugar or flour.

If a patient has a desire for a dish of chocolate ice cream, for instance, I instruct him to immediately picture that ice cream "glued" into disgusting fat deposits on his abdomen. This picturing takes place while the patient is in an altered state of consciousness, such as that of deep relaxation, meditation or hypnosis. With sufficient repetition of such imaginary scenes, this "disgust" feeling becomes associated with that type of food in real life encounters.

The patient is further instructed to deliberately and instantly, throughout his waking life, react to every real life reminder of his enemy foods with this strong vivid disgust response. He then immediately rewards himself with a sense of being in control, "captain of my ship" and anticipating his trim self-image.

This use of an interference response coupled with disgust, and then immediately followed by a reward for deliberately feeling negative toward the enemy foods, has proven of great value in preventing relapse. We call that our "instant yuk" technique. It only takes a couple of seconds and it can be repeated for years.

Once the addiction is under control, it becomes much easier to retrain such fattening habits as eating too

fast, eating until too full, and frequent snacking. It appears that these habits are fueled by the presence of addictive cravings. They fall away readily after the fire of cravings is extinguished.

Also, many patients find that they no longer have the habit of eating when under psychological and emotional stress. The cravings of an addicted person, regardless of the substance of his addiction, are regularly mobilized when the individual is in an excited state—when he is "turned on" by any challenging stress, joy, anger, anxiety, tense depression, tense boredom, etc.

Most patients who have successfully extinguished their addictive state, including their conditioned cravings, do not have a flare-up of their cravings under such psychological and emotional stress conditions.

These successful ex-addicts are frequently surprised and pleased to find that they are not as weak, insecure and neurotically self-destructive as they believed they were during their addictive period.

Since this therapeutic approach eliminates major sources of former eating pleasure, the treatment must stress that a successful outcome is a gain and not a deprivation.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > Article #4: Well! You Wanted to Know by Vivian V. Vetrano

### **Article #4: Well! You Wanted to Know by Vivian V. Vetrano**

**How often should one fast to counteract bad foods that were eaten? Is it better to fast one day per week, or three days per month, or what way is the most beneficial for maximum health?**

First of all, one should not eat foods that are refined or that are not wholesome. If you happen to be in a situation that causes you to eat unwholesome substances then, of course, one has to do something to counter the detrimental effects of his or her misbehavior. There are several ways one may counter misbehavior. You may use one method, or either of them, according to the situation. After you have had a binge, you will be in high gear (stimulated for about a day), until the body has eliminated the poisons. You may not feel bad until the second day after the binge. In this case it is wise, especially if you have eaten refined products, to eat a salad at each meal, containing a great deal of lettuce, the day after the binge. Then the second day after the binge you may fast, for that is the day you are going to be in low gear. That is, you will feel miserable and tired from having been stimulated by the unwholesome substances. It will help to be able to stay at home and rest completely while fasting, the second day after the binge.

Some people have their low the very next day after a binge. It is very similar to a hangover. They feel tired, out of sorts, depressed and their aches and pains, if they were suffering with any disease, will be worse. If your low comes the very next day, it is best to fast at this time and rest, for if you don't, having had junk food and not being very hungry and tired to boot, you will tend to go to junk food again to stimulate yourself to get through a completely terrible day. If you have a tendency to repeat the act, then it is best to cease eating altogether and rest and fast the very next day after the wrongful thing you have done to your beautiful organism.

If you are eating bad foods all the time, you must not fast every other day, or even two or three times a week. You must not fast to counter this situation. You will keep yourself in a hungry state all the time and because you refuse to let yourself eat good food but continue

trying to force yourself to fast, each time you misbehave, you will set up a cycle of being hungry because you won't let yourself eat good food and you will always go out and binge. This is a similar situation to people who have a hard time losing weight. They can't lose weight while eating Hygienically when eating fruits so they deny themselves nice juicy sweet fruits only to get a carbohydrate hunger; so they go out and eat candy and other refined carbohydrates. Whereas, if they had permitted themselves a little bit of fruit, and fasted one day a week, they would lose weight, and would be preventing themselves from the cycle of binging on sweets.

if you get into the habit of eating poisoned and refined foods often and think you can undo the evils of this way of life by fasting, you are mistaken. Even though you may fast to help eliminate the poison, your body has done double work. It has to expend energy trying to digest the poisonous substances. Then it has to expend energy to eliminate the poisons. It has lost minerals and vitamins in both processes. The fast itself causes an extra expenditure of energy because of the extra work it has to do to compensate for the binge. The grand total is negative and equals enervation and a loss of reserves.

It is really a bad policy to think you can overcome the effects of wrong living by fasting. Even though the body can overcome many of the detrimental effects, normal cells are destroyed in the process and the end result is still negative. You cannot build positive vibrant health in this manner.

For maximum health one does not have to fast unless injured or unless there is an acute crisis of some sort. If you live genuinely Hygienically, all you need, because of a polluted environment, is a once a year rest and "tune-up" fast of about eight to fourteen days. If you live in the country, away from all types of pollution, you may not require a fast of that length.

Fasting one day a week may be too much for some people. They may not be able to gain weight, or muscle by fasting this often. Fasting three days a month, for no reason at all, is not necessary. Fasting should be used instinctively. When your hunger is absent, fast. As long as hunger is present and there is no biogony or physical or mental problem then there is no reason to fast. Just live *Hygienically*.

**What about the most efficient cleanser to use daily—intestinal cleanser, yeast cakes, or granulated yeast, juice, lemon juice with salt water, vinegar and maple syrup and cayenne mixture?**

You don't need an intestinal cleanser or otherwise. The lining of the entire gastrointestinal tract is self-cleansing. The mucous membrane, from the mouth to the anus, contains what are known as goblet cells. When filled with mucus these cells look like goblets. Their purpose is to secrete the mucus to keep the lining of our food tube moist and clean. Debris does not collect inside the intestinal tract because the mucus keeps the surface slippery, and peristalsis keeps the food waste moving along toward the anus, where it is voided.

Pay no attention to the sales pitch for colonics and intestinal cleanser, for our intestines are self-cleaning and crusts can't accumulate in the intestines. All of the substances that are considered cleaners are in reality dirtiers. They are not foods and do not belong in the intestinal tract where they may be absorbed and dirty the system. Salt is a poison; yeast cakes and granulated yeast are not digestible and are harmful; vinegar has acetic acid and alcohol in it which are poisons; maple syrup is a cooked product and not good for you; and cayenne pepper is a poison that damages the liver and kidneys and irritates all the tissues with which it comes in contact. The only substance that is not poisonous is lemon juice, but

since foods don't cleanse the living organism, that is, the living organism alone cleanses itself, why fool yourself?

Don't eat bulkless substances. Just eat natural fresh fruits, vegetables and nuts and your intestinal tract will always be clean.

[Home](#) > [Lesson 44 - Overeating: Fasting Fanaticism And Diet Fanaticism](#) > Article #5: Why I Don't Fast To Lose Weight By Marti Fry

### **Article #5: Why I Don't Fast To Lose Weight By Marti Fry**

I have a tendency to overeat because I, like so many others, greatly enjoy eating. I find it difficult to consistently control myself when it comes to how much I eat and how often. It takes determination. It also takes pursuit of other activities, such as studying, hiking and conversing, that give me my "kicks" in more wholesome ways than "recreational eating."

I was about ten pounds overweight a couple of years ago, and, on my small frame, it looked like a lot because the fat concentrated around my middle. I fasted every week for one to three days and lost my extra weight—but I gained it back when I stopped my weekly fasts because I was accustomed to eating too much on the days when I wasn't fasting.

Next I tried a single long fast for a couple of weeks. Again I lost my extra weight. But, again I gained it back, this time because I had such a raving appetite and experienced such a keen enjoyment of my food. (Food tastes better after a fast because of the enhancement of our sensory perceptions when we are less toxic.)

I spoke with Dr. Vivian V. Vetrano, a professional Hygienic practitioner, about my problem of keeping excess pounds off. She recommended that I stop fasting to lose weight. Instead, she said, I should develop good daily habits. She advised me to eat slightly less than I would for weight maintenance, to refrain from snacking, to engage in daily vigorous exercise, and to get plenty of rest and sleep. She said I would lose about two to three pounds a week and keep it off.

I didn't lose two to three pounds a week. In fact, I lost only about a pound a week because I didn't cut down on how much I ate as much as I should have. But I did lose weight—and I did keep it off!

In the last month or so I gained a couple of extra pounds. I fasted for 36 hours last week and lost them. But, after the fast my appetite was enormous. It took larger portions of food to fill me up, and I got hungry more often. This lasted for a couple days after my fast. My appetite was great and my eating capacity was temporarily increased.

Eating more heavily and more often than normal immediately after my fast got me started on a bad habit of overeating. Not only did I regain the weight lost, but I also gained an extra pound or two! So now it's time for me to forget about fasting and get back in the habit of moderate eating every day.

Note: Many people find fasting to be the easiest, quickest, and most effective way to lose weight. Others, like myself, find it better not to fast to lose weight. But all people keep their weight off by healthful living and eating habits.

## **Article #6: Help! I Can't Stop Eating**

We often read that vegetarians, particularly total vegetarians, are slimmer than the population averages. Statistically, this may well be so, but anyone who is a compulsive overeater knows that whether on an omniverous or vegetarian eating plan, it is often impossible to stop pushing in the food.

Guilt and self-recrimination follow every binge, and well-meaning friends are always on hand with their favorite diet tips. But the tips don't help, even if pride allows us to accept them. That's because we've been on all the diets, to the doctors and the fat farms and the hypnotists and faith healers—but that first fatal bite always leads once again to uncontrollable gorging.

I would like to share what has helped me recover from this tragic illness: the 12-step program of Overeaters Anonymous taken directly from the time-honored Alcoholics Anonymous program. We use their steps to recover on the physical, emotional and spiritual levels, and we read the A.A. literature, simply substituting the word food for alcohol and compulsive eater for alcoholic. O.A., a fellowship which has no dues or fees, is wonderful for vegetarians because it is not a diet club and does not deal in diets, many of which would exclude a vegetarian from the start. Because we have come to believe that most of the fat is between our ears, the program works to help change our thinking so that we no longer want to overeat. That's the beauty of it: it's the miracle every compulsive eater has long dreamed of, to eat all he/she wants and maintain a normal weight. It's only possible when all you truly desire is a normal amount of decent food.

Overeaters Anonymous is listed in telephone directories of most major cities. No one is too fat or too thin to recover. O.A. recognizes that anorexia nervosa, self-imposed starvation, and compulsive vomiting are other aspects of the basic disease of compulsive eating: a physical allergy to certain foods and large amounts of food, combined with a mental obsession that enslaves the victim to his/her addiction.

My own recovery has resulted in a slender body (a 68-pound weight loss maintained for two years, quite a miracle for a former yo-yo dieter), the indescribable joy of freedom from cravings and food fears, an emotional poise that I would never have imagined possible, and truly high-quality vegetarianism. Prior to embarking upon recovery from compulsive overeating, I felt like a hypocritical vegetarian: who would want to give up meat if I were their only example of a vegetarian, a person physically unhealthy and emotionally unstable? Recovery has also meant that I've been able to become a vegan, something I'd wanted to do for several years but was not able to accomplish because of my love affair with a variety of foods.

You will notice that there is no name given for the writer of this article. That is because O.A. members remain anonymous at the public level. (When I share my program, I as an individual am not important; it's a matter of "principles before personalities." I keep my program and further my recovery by giving away what has been given me. I am responsible for extending the hand and heart of O.A. to all who share my condition, and that service orientation expands to enrich my family and professional life and my work for vegetarianism.)

If your eating is destroying your world instead of nourishing your body, there is a solution. It's a tragic, disease, but a beautiful recovery.

—Anonymous

- [Article #2: Fasting In Nature By Dr. Alec Burton](#)

### 1. What Is Fasting?

There are many definitions of fasting and there are many misunderstandings about fasting.

The word "fasting" is derived from the Anglo Saxon language and means "firm" or "fixed," the word being "faest," and during these early periods the practice of abstaining from food during certain periods was referred to as fasting. Therefore, it was related to a person firmly withholding food.

From our standpoint, fasting refers to abstinence from food in the total sense. Commonly, and in many religious organizations, fasting refers to abstinence from certain prescribed foods.

In certain quarters, the common language usage is to refer to certain specific foods, and a person may be said to be on a "juice fast" when they are subsisting on juices. In actual fact, these are juice diets.

Fasting in the broad sense may be regarded as negative nutrition compelling the organism to subsist on nourishment that it has stored within itself.

For the purposes of this course, fasting means the voluntary and complete abstinence from all food except water while nutritional reserves remain adequate to sustain life and normal function.

#### 1.1 Fasting vs. Starving

It is important also to make a clear distinction between fasting and starving.

The word "starve" is also derived from the old English word "steorfan" which means "pestilence," "mortality." Therefore, to starve is to die, and this is what will quickly happen if nutritional reserves are exhausted.

Therefore, we must fully understand that fasting represents a process of utilizing nutritional reserves while abstaining from eating. Conversely, starvation represents a state where the nutritional reserves have been exhausted and the organism's vital tissues are rapidly being broken down.

## 2. History Of Fasting

Fasting has a long history, but much of it is associated with religion. There are over 30 references to fasting in the Bible. There are numerous references to fasting among non-Christian religious groups. As a religious observance fasting has been practiced for centuries, and it undoubtedly, as a practice, preceded recorded history.

It is evident from records that exist that abstinence, either partial or complete, from all food or from certain foods, existed in Assyria, Babylon, China, Greece, India, Palestine, Persia and Rome, and the records from the early civilizations of Mesopotamia and Egypt indicate that fasting of some type was an important part of religious practice. However, I would refer the reader to other literature to investigate this aspect of fasting because here we are more properly concerned with the utilization of fasting as a means of recovering and preserving health.

We are interested in therapeutic fasting and I use the word "therapeutic" in the original sense and this is important.

"Therapeutic" is derived from the Greek language and means "to attend," "to minister," "to tend the sick." It does not necessarily mean to employ a range of treatments called therapies.

So our preoccupation with fasting relates to the application of fasting as a health measure.

Aside from religious fasting it has also been associated with magic, with specific disciplinary practices, with exhibitions for the sake of notoriety, and also in the twentieth century especially with hunger strikes. The recent incident involving Bobby Sands and his comrades in Northern Ireland has given a lot of publicity to the subject. However, these and other uses of fasting have little to do with our consideration of fasting as a scientific procedure involved in the care of the well and the sick.

During the last hundred years or so, the subject of fasting has undergone close experimental and scientific scrutiny which was probably initiated by the famous physiologist, Dr. Francis Gano Benedict of the Carnegie Institute in Massachusetts. His book, *The Study of Prolonged Fasting*, is well worth close perusal today.

In more recent times, Dr. G.F. Cahill has made enormous strides in our understanding of the physiological and biochemical mechanisms of fasting. It has been only over the last 150 years or so since the development of the hygienic system that fasting has been employed as a serious and satisfactory health procedure, and the work of these remarkable pioneers has added greatly to our understanding of the clinical aspects of fasting and the remarkable benefits that are available to the sick through its employment.

A brief review of some of the giants of hygienic history may be relevant here, for it was through these people that the employment of fasting became a fundamental practice in the hygienic care of the well and the sick.

Dr. Isaac Jennings was born in Fairfield, Connecticut, in 1788, and after many years of conventional medical practice, he made an enlightened discovery. That was in the year 1822 when his ideas as a result of his experiences and observations radically changed and he came to the sudden conviction that "medicine is a gross delusion from beginning to end." He developed and taught a philosophy which he called "Orthopathy," which he claimed expressed his conception of the essential nature of disease. Dr. Jennings lies at the beginning of a new movement, a health reform movement, which took place not only in the United States but also in Western Europe. It was subsequently absorbed into the hygienic system. One of Dr. Jennings converts was Dr. William Alcott from Boston, a second cousin of Louisa May Alcott who wrote the classic novel *Little Women*.

Dr. Alcott was a prolific writer and expounded the principles of diet reform, vegetarianism, and other

major ingredients of the health revolution.

Dr. Thomas Low Nichols and his wife, Mary Gove, were influenced by the reformatory and inspiring lectures and teachings of Sylvester Graham, a preacher of the early nineteenth century who based his health reform principles on basic physiology.

Dr. Nichols and his wife became avid supporters of the hygienic movement and its practices.

In the mid-nineteenth century a magazine entitled *The Laws of Life* was edited by Dr. Harriet Austin who was among the first four women to graduate in medicine in the United States. She was associated with another famous hygienist, Dr. James C. Jackson. Both of these fine practitioners were enthusiasts of hygiene and especially fasting, and Dr. Austin herself was vigorously active in women's reform movements.

Another contemporary was Dr. Susanna Way Dodds, and these two women brought about a great deal of health reform in the latter part of the nineteenth century.

Dr. Dodds actually established a major college in St. Louis, Missouri, in 1887, and she wrote extensively on the subject of hygiene.

Among all of these eminent figures arose one man who displayed a remarkable ability for referring arguments back to first principles.

Here, I allude to Dr. Russell Trall, a most prolific writer, who expounded his revolutionary ideas with vigor and clarity. His many books, some of which have been reprinted recently, make vitally important reading for the student of hygiene and fasting.

Among the many hygienists was Dr. Edward Hooker Dewey who was born in Pennsylvania in 1849 and developed a strong advocacy of fasting. He wrote a number of books, one being *The No Breakfast Plan* which introduced the subject of fasting. Even at this time the development of the science of physiology was supporting the employment of fasting.

In this connection, the famous Dr. Beaumont did a lot of useful experimental work on a North American called Alexis St. Martin. This gentleman has sustained a gunshot wound in the abdomen and the lesion was open into the gastric cavity. As a result of this, Beaumont was able to observe the digestion of various foods and the change in the gastric juice constitution under different conditions, and I quote Beaumont.

"In febrile diatheses very little or no gastric juices are secreted, hence the importance of withholding food from the stomach in febrile complaints. It can afford no nourishment, it is actually a source of irritation to that organ, and consequently to the whole system. No solvent can be secreted under the circumstances and food is insoluble in the stomach as lead would be under ordinary circumstances."

Beaumont reports that food had lain in the stomach of Alexis St. Martin from six to fourteen hours unchanged except by decomposition, that is, by fermentation and putrefaction.

Beaumont also made reference to the old adage "feed a cold and starve a fever." Unfortunately, this particular saying has undergone considerable change over the centuries. When it was first uttered, it stated "feed a cold and you will have to starve a fever." This was subsequently shortened which has entirely altered its meaning and implication.

Another illustrious hygienic teacher was Dr. Robert Walter, born in 1841. Like Graham, Trall, and many others, he had the exceptional ability to understanding the law of causality. He practiced in Pennsylvania, possessed a brilliant mind, was a keen thinker, and a careful logician. He made a great contribution to our understanding of health and disease.

Dr. Charles E. Page was born in 1840. He studied medicine during the Civil War and wrote extensively on the subject of hygiene and fasting. He also made valuable literary contributions to numerous magazines as well as extolling the virtues of fasting in the care of children.

In the late days of the nineteenth century a man arrived from Belgium, born in 1845. His name was Dr. Felix Oswald, and among his numerous writings was one book entitled *Fasting, Hydropathy and Exercise* which should be of more than passing interest to any student of the subject.

Dr. John H. Tilden was born in Illinois in 1851. He graduated in medicine in 1872 and wrote extensively on health, disease, diet reform, and numerous procedures and techniques employed in the care of the sick. Among these techniques was fasting. Most of Dr. Tilden's major work and writing took place during the twentieth century, and his magazines and books are full of epigrams and philosophies which depict his clear and penetrating mind. At his clinic in Denver, he regularly employed fasting as a means of care.

An Englishman, Dr. Henry S. Tanner, made fasting somewhat popular. He underwent a number of fasts, the first undertaken in 1877 which I believe lasted for fourteen days. Later Dr. Tanner experimented with a fast of forty days. His experience gave a clear understanding of the need and importance of water during fasting. From the information I have, his initial fast was without water, with rather serious consequences.

Discussing the work of many able men in the twentieth century, we should seriously investigate the work of Lief, Thomson and Shelton. Dr. Stanley Lief traveled from England and was educated in the United States. He returned to Britain around 1912, and throughout his life had extensive experience with fasting, conducting numerous clinics where the procedure was employed. He encouraged and recommended long fasts, but not without competent supervision and had remarkable successes despite strong medical opposition.

Dr. James C. Thomson, a Scotsman, also went to the United States for his education. He returned to Scotland around the same time that Dr. Lief settled in London. He practiced in Edinburgh for many years and later established the famous Kingston Clinic. While an advocate of fasting in the short term and especially in febrile conditions, he was not enthusiastic about long fasts.

Dr. Herbert M. Shelton, the leading American hygienist, has properly had more experience with fasting than any other living authority. He has written a number of books on the subject which are highly recommended, and for many years conducted Dr. Shelton's Health School in San Antonio, Texas, where fasting was the fundamental procedure employed in the hygienic care.

Another prodigious worker for the twentieth century with a wide experience of fasting was Dr. Linda Burfield Hazzard. Her book, *The Fasting Cure*, is valuable and expresses a wide experience of the subject. Not only was her experience of fasting extensive, but she was thoroughly familiar with the long fast, which demands much more understanding and supervision than those of short duration.

In our consideration of the hygienic movement with special reference to fasting, it would be incomplete and inexcusable not to mention the current hygienists whose knowledge and experience is both wide and detailed.

Dr. William Esser had been in practice for almost fifty years and conducted an institution in Lake Worth, Florida.

Dr. Robert Gross has been active in the movement for several decades and conducts an institutional practice at Hyde Park, New York.

Dr. Gerald Benesh, who has now retired, was for many years vigorously active in both Cleveland, Ohio, and later in Southern California. Today, in the Cleveland area, Dr. David Scott operates an extensive practice employing fasting as a basis for hygienic care.

As a result of the urgent need to exploit the experience and knowledge of a number of unique individual professionals, in 1978 an organization was established—The International Association of Professional Natural Hygienists. This comprises professionals who have specialized knowledge of the value and employment of fasting. They are familiar with its processes and they are competent to conduct fasts in all states of health and disease where indicated. A list of members of this singularly important

organization is available upon request.

[Home](#) > [Lesson 45 - Introduction To Fasting](#) > 3. Why We Should Fast

### **3. Why We Should Fast**

Fasting represents a physiological rest and to make this point more lucid, we may look at the process of bio-energetics. When we consume food, the initial process is of ingestion, the placing of food into the mouth. This is followed by the process of mastication and swallowing as the food initially prepared within the oral cavity departs for the stomach where it is once again acted upon by the mechanical pressures of the muscular contractions of the stomach wall combined with the chemical effect of the secreted products referred to as gastric juice.

After a period of time ranging from one to several hours, the food is then actively transported into the duodenum where it undergoes further mechanical and chemical processing before it traverses the canal to a point where it may be absorbed—a process referred to as "active transport."

Whatever remains behind travels through the tract to the bowel and is expelled. The nutrients which have been absorbed are circulated and processed by the liver and other organs. Some may be stored and others directed to the cells for utilization.

If we look closely at this whole process, we will observe that ingestion, mastication, transport, gastric secretion, and mobility, intestinal secretion and activity, bowel action, absorption, circulation, storage, distribution, and final assimilation within the cell are energy expensive processes. Right to the point where the molecules of the nutrients are enzymatically broken down and energy is liberated, right to this point energy has been expended.

We can now see that in fasting-much of this energy does not have to be expended. In fact it is conserved. First, the nutrients are already in the body. Although they may be stored and subject to reconversion, they are nevertheless beyond the point of absorption, and are therefore more easily available to the body with a minimum energy expenditure. At the same time another grand process of the body is elimination. That is, the particular process by which metabolic toxins (by-products of normal bodily processes) are eliminated from the body.

As you have learned, the living organism is constantly producing toxins. These are substances which are the end result of the body's chemical processes, and it is essential that they may be removed from the tissues and the blood as rapidly as they are produced. This is the process of elimination which is accomplished largely by the kidneys in producing urine, by the liver in producing bile, by the lungs in exchanging gaseous wastes.

In this total process then, we can argue that fasting represents a physiological rest, in that less energy is required for the utilization of nutrients when fasting than under normal conditions of feeding, and that as a consequence, more energy is available for the restorative and recuperative effort that the body is to make which involves increased elimination among the many processes.

#### **3.1 Accumulation of Waste Products**

We must bear in mind that the average person in this country eats far more food than necessary, exercises far less than needed, and rests far too little. All of these changes result in a build-up of unwanted waste material in the body. For instance, consider fat. When a person eats too much fat, the level of fat in the bloodstream becomes elevated. When there is too much fat in the bloodstream, some of it diffuses into the space between the blood vessels and the cells. When there is too much fat in this

space, called the intercellular space, some of the fat diffuses across the cell membrane into the cells.

The result of having too much fat in the bloodstream, too much fat lining the blood vessels, in the intercellular spaces, and inside the cells, is to interfere with normal functioning of the cells. This excess material partially blocks the exit of carbon dioxide and other waste materials from the cells. Poor functioning, called disease, is the inevitable result of this situation. The type of disease depends on the location in the body in which the greatest amount of fat has accumulated.

### **3.2 Chemical Wastes Commonly Found in Excess**

There are many waste materials, excesses, and other toxins that accumulate in and around cells and blood vessels and cause harm. Consider some of the chemicals that are commonly present in the bloodstream, but cause harm when present in excess quantities.

Cholesterol is one problematic substance. A certain amount is needed for normal functioning. Excesses, however, set the stage for heart disease.

Triglycerides are the fats in our diet and bloodstream. When present in normal amounts, there are no problems. However, excesses also contribute to the cause of heart disease.

Uric acid causes harm when its concentration in the bloodstream rises too high. Gout may result when this occurs.

Glucose (blood sugar) is needed for normal functioning. But, when a person is diabetic and the blood glucose level remains abnormally low, much harm will result.

The fact is that any chemical substance, if present in too great an amount in the body, will cause problems, such as cholesterol, but also chemicals which are not normally present, such as cadmium (strictly speaking, this is a metal, not a chemical).

If any food, even protein (it might be more accurate to say especially protein), is eaten in amounts exceeding the body's ability to burn up or eliminate, it will accumulate and cause problems. When a person exercises too little, less food is burned and health problems can thus more easily develop.

Finally, when a person is under too much stress or gets too little rest, the body has little energy to devote to the process of elimination.

### **3.3 Unimpeded Elimination Essential**

Consideration of the subject of fasting brings attention to a major, but usually neglected, area of nutrition and biochemistry—that of elimination. Most nutritionists are only concerned with supplying the body with enough food; they give little attention to the damage brought on by too much food and too little elimination of waste.

Imagine the body's metabolic systems as a funnel. Only a certain amount of food can pass through the small end of the funnel. In the body, this means that only a certain amount of food can be burned by the body to form energy, carbon dioxide, and water; also, the body's eliminative systems (intestines, liver, kidneys, lungs, skin) can only eliminate a limited amount of excess food. Therefore, when too much food is poured into the funnel, there is a backup. First the bloodstream, then the intercellular spaces, then the cells become loaded with excesses. This condition is called tissue constipation and toxemia.

In society, there is a tremendous concern for intestinal constipation. Yet, the scientific research shows that the main cause of discomfort from the intestinal constipation is from the pressure it causes, not from chemical poisoning from the colon. Compare this to the condition of tissue constipation: here we have a build-up of many harmful chemicals to which all our cells and tissues are exposed. Tissue constipation is hundreds of times more damaging than colon constipation.

And this is where fasting enters the picture. While fasting, the body can remove the chemicals

responsible for tissue constipation and toxemia, the very chemicals responsible for a wide variety of diseases.

[Home](#) > [Lesson 45 - Introduction To Fasting](#) > 4. The Body's Innate Wisdom Guides Us During A Fast

## **4. The Body's Innate Wisdom Guides Us During A Fast**

When a person is fasting, his heart and lungs and kidneys and other essential organs continue functioning. They must be functioning or death would rapidly ensue. To function, these organs need fuel. While eating, this fuel comes from ingested food, yet this source is obviously not available during a fast. While fasting, all nourishment is supplied from within the body.

Hygienists have long recognized the wisdom behind the functioning of the body. To maintain the blood acid/alkaline balance, or the blood sugar levels, or the body temperature, or the blood pressure level, requires tremendously complicated physiological systems. That the body is able to maintain itself in a steady state, called homeostasis, even when there are great pressures to deviate from this state requires properly functioning mechanisms which are far more complicated than the finest engineer or computer scientist could design.

Yet, there are some scientists who believe that when a person is fasting his body lacks the intelligence and self-protective mechanisms to break down nonessential material within the body first, and thereby spare the essential tissues.

Scientific studies, however, along with the accumulated experiences of 150 years of Hygienic doctors, testifies to the contrary. The body's innate wisdom continues functioning during a fast. The body is well aware of the fact that tissue constipation and toxemia are interfering with its normal functioning.

In fact, even while eating the body is attempting to break down and remove the waste material in and around cells and blood vessels. During a fast, however, this process is greatly accelerated. The body at this time needs to devote no energy to digestion and absorption of food. This energy, therefore, is devoted to elimination of waste.

### **4.1 Nonessential Matter is Utilized First**

Fundamentally, fasting is as simple as this. While fasting, the body breaks down and burns for energy the least essential substances within it first. After a period of weeks (2-6 weeks in the nonobese person), this process is completed. When all waste material and nonessential substances (fat reserves) have been eliminated, the fast is finished. If a person continues not to eat, he will be starving. During this period of time, the body will break down and burn for energy its essential tissues. A doctor can easily tell when a fast ends. The way in which this is done will be discussed in future lessons.

Scientific research has totally confirmed this metabolic scenario. When the average person begins to fast, the body initially will burn for energy the glycogen which has built up in the liver and muscles.

This glycogen, formed from blood sugar (glucose), is present in only small quantities. Once the glycogen stores are exhausted, which occurs in just a few days, the body will burn mainly fat, a non-essential reserve material which has accumulated not only in the thighs and buttocks but in and around every cell and blood vessel in the body. After the fat is gone, the body will begin to burn the protein which is in excess.

## 4.2 The Body Conserves Its Vital Organs

For many years, scientists believed that the brain could only live on blood sugar. This is important in the discussion of fasting for the following reasons. First, the brain usually burns 20% of the body's blood sugar; it is, therefore, a major consumer of energy materials. Second, if it can only live on blood sugar, this must be supplied to it while fasting. Third, while fasting, after the glycogen stores are used up, the only source of sugar is from breakdown of protein. Fourth, if protein is used to supply the brain with sugar from the beginning of a fast, there must be a tremendous breakdown of liver muscle to feed the brain. And fifth, if this occurs, fasting for over a few days will be exceedingly dangerous.

It is for this reason that scientists criticized fasting prior to 15 years ago. But about 15 years ago, scientists found that during a fast the brain will undergo metabolic conversions so that it can burn fat. This spares blood sugar, which in turn spares body protein (mainly muscle and liver), which in turn vastly prolongs the amount of time during which a person can safely fast.

For 135 years, Hygienic doctors had claimed that the average person can safely fast for about 2-6 weeks with little or no loss of essential tissue. In the last 15 years, conventional nutritional scientists have finally come to adopt this view. But beware of those doctors and researchers who have not read a textbook or scientific journal published in the last 15 years; they will still say that the brain can only live on sugar and that fasting is therefore dangerous! You would be surprised to know how many doctors are not aware of the research which has been published in the last 15 years.

[Home](#) > [Lesson 45 - Introduction To Fasting](#) > 5. What The Body Does When You Fast

## 5. What The Body Does When You Fast

So, what does the body do when you fast? Dr. Shelton lists four main activities.

1. Breakdown of body fat, thereby leading to rapid weight loss. This is beneficial because excess body fat increases the risk of heart disease, strokes, cancer, diabetes, arthritis, and many other diseases. Fasting is the "fastest" way to lose weight.
2. Diversion of energy from digestive processes to other tissues where needed for repair and rejuvenation. Dr. Shelton explains that "if you have the water running in your bathtub and somebody turns on the water in the kitchen sink, the rate of flow into the bathtub is immediately diminished. When the water in the kitchen is cut off, the rate of flow into the bathtub is immediately increased." When digestion is suspended for a period of time by fasting, far less blood flows to the digestive organs. This blood is then free to flow to other tissues in the body, bringing with it essential oxygen and other nutrients which are needed for healing. This extra blood also serves as the vehicle in which wastes can be carried away.
3. Physiological rest is secured. We all know the importance of rest after a hard day's work. At night, we fall into bed exhausted. If we do not secure a good night's rest, we will function poorly the following day. Our internal organs need rest also, yet we almost never give them rest since we eat every few hours every day. By fasting, an opportunity for complete rest is given, and the internal organs thereby are able to rebuild their strength.
4. Fast to eliminate wastes. Again quoting Dr. Shelton: "Nothing known to man equals the fast as a means of increasing the elimination of waste from the blood and tissues. Only a brief period elapses after food is withheld until the organs of elimination increase their activities and a real physiological housecleaning is instituted."

## **5.1 Cholesterol Deposits Break Down**

In regard to elimination of wastes, consider the situation with cholesterol. Most of the cholesterol stored within the body is lining the blood vessels, setting the stage for a heart attack or stroke. While fasting, a person is obviously ingesting no cholesterol in food. Therefore, there is no added dietary cholesterol entering the bloodstream. Yet, blood tests show that the level of cholesterol commonly goes up during the first 7-10 days of a fast, then decreases afterwards. Where is this cholesterol coming from? Scientists believe the source is deposits of cholesterol in the blood vessels. The body, in an effort to cleanse its blood vessels, breaks down the deposits of cholesterol in the blood vessels and liberates it. This cholesterol is either used (to build new cell membranes, to form adrenal hormones, or other such functions) or eliminated by the liver in the bile. This is an excellent example of the body's accelerated elimination during a fast.

## **5.2 Fibrinolysis**

Another body function that increases during a fast is fibrinolysis. Clots in the bloodstream are usually covered by a meshwork much like a spider's web called fibrin. These clots are extremely dangerous: if one lodges in a small blood vessel in the lungs, the blood supply to that part of the lung will be obstructed and part of the lung may die. The clot is called a pulmonary (for lung) embolism (traveling clot). The process is called pulmonary infarction (death of part of the lung).

While fasting, the body's ability to dissolve clots is greatly increased. This process, called fibrinolysis, does not permit such problems as pulmonary embolism and is part of the body's effort at healing such problems as thrombophlebitis (inflamed veins, usually in the legs, where clots often form and break loose to travel to the lungs).

## **5.3 Autolysis is Accelerated**

Also during fasting, the process of autolysis is accelerated. Each cell in the body contains the seeds of its own destruction. When the need presents, itself, the cell will release its own self-destructive enzymes and self-destruct. This is autolysis. As stated earlier, the body will break down and burn nonessential substances first for energy while fasting. One source of nonessential material is diseased tissue such as benign tumors (fibroid tumors of the uterus are a good example). During the fast, the process of autolysis leads to the breakdown of this type of tissue which has hampered normal functioning.

## **5.4 Increased Diuresis**

An important body activity during a fast is greatly increased diuresis. Diuresis is the excretion by the kidneys of salt and water. Medical doctors give diuretic drugs to high blood pressure patients in order to decrease the amount of salt and water in the body, which will then result in lower blood pressure. Diuretic drugs, however, damage body tissues. While fasting, the body spontaneously and automatically eliminates salt and water without damaging body tissues. This diuresis is of tremendous health benefit.

## **5.5 Phagocytosis Is Accelerated**

The list could go on forever. While fasting, the ability of the body's defensive army of white blood cells to destroy virulent bacteria and digest waste material is accelerated. An experiment compared the ability of these cells to destroy virulent bacteria when taken from the bloodstream of someone who had been eating, versus cells from someone who had been eating, versus cells from someone who had fasted for a few days. The white blood cells from the fasting person were significantly more effective at killing virulent bacteria.

## 6. Juice Dieting Vs. Fasting

There are some people who advocate juice dieting over true fasting, saying that it is safer and healthier. We can dismiss the safety claim, since true fasting is safe if done the proper way under experienced supervision. We can also dismiss the claims regarding health. (While it is true that much less energy is expended when a person is on a juice diet than when they are eating solid food, however, when no food is taken at all (solid or liquid), the conservation of energy is greatest and the healing potential is therefore also greatest.—ed.). Therefore, we have objective evidence that there are more health benefits from water fasting than from juice dieting.

The general conclusion is that while fasting, the body's healing and repairing and rejuvenating and eliminating powers have more energy and resources to do their work effectively, efficiently, and rapidly.

## 7. What A Fast Cannot do

But can a fast do everything? Can a fast heal any health problems? First of all, let's consider the implications of this mistaken terminology which is in widespread use.

A fast does nothing! A fast only provides a condition during which the body can effectively build its health. Don't think of the fast as an independent actor with a life of its own. This is a carry-over from mistaken medical thinking which claims that drugs act on the body. Drugs do not act in the body. They are inert and lifeless! In fact, the body acts on the drugs. The one and only actor at all times, in health and disease, regardless of diet or drug, is the body. This is totally the case while fasting. The body acts, not the fast. The fast only provides the proper condition.

So, instead of asking "what can a fast not do," we must ask what can the body not do while fasting. The body does not have unlimited powers of healing. As the lifespan progresses, the powers of healing diminish. An adult, for instance, can only rarely display the physiological vigor seen in an infant in regard to fever. A fever is a defensive measure intelligently initiated by the body. When the body raises its temperatures to higher levels, greater amounts of waste are burned up. An infant's healing power is so vigorous that it can raise the temperature to high levels in a short time. Yet an adult, whose healing powers are relatively weaker, cannot mount such an intense defensive action. An adult's fever rarely reaches the height seen in an infant.

The limited ability of the body to heal itself determines the extent of healing during a fast. This power of healing is far greater than most people realize, so it could be a grave error to decide, without consulting a Hygienic doctor, that there is no hope in any individual case. Yet it is equally erroneous to indulge in inane optimism and claim that the body is capable of healing and resolving any problem during a fast. Totally destroyed tissue in a joint, as seen in very advanced cases of arthritis, can usually not be reconstituted even under the best conditions as provided by a fast. Hygienists have found that the body is not usually able to destroy malignant tumors while fasting, nor can it rebuild the "insulation" around nerves that has been destroyed in multiple sclerosis.

But the happy truth is that the vast majority of human illnesses can be helped by fasting. Fasting, in fact, provides the best opportunity for the body to heal itself. Yet the body does not have unlimited powers of self-repair. An experienced professional Hygienic doctor is able to judge in any individual case what the prospects are for recovery.

In future lessons, we will discuss the specifics of which conditions are helped by fasting; all the aspects of managing a fast; how to break a fast; and how to live after a fast.

[Home](#) > [Lesson 45 - Introduction To Fasting](#) > 8. Questions & Answers

## **8. Questions & Answers**

### **What is the difference between fasting and starving?**

People who are ignorant of the subject say there is no difference. In fact, there is a large difference. Fasting is the period of time during which a person is ingesting no food, but is living off of nonessential reserve material inside his body. Starvation begins when all non-essential reserve material has been used up, and the body must therefore begin to break down and burn for energy essential tissues.

### **What does a fast do?**

A fast does nothing. A fast only provides a condition in which the body can more rapidly and effectively heal and normalize itself.

### **Is there very much scientific research on fasting?**

Yes. From the early 20th century up to the present time, a tremendous amount of research has been done on fasting. Many papers have been published in the finest scientific journals. Scientists have a profound understanding of the biochemistry, physiology, and metabolism of fasting.

### **Why do many people say that fasting is not safe?**

Mainly because it is emotionally objectionable to go without food, since food means love and comfort and security to most people. Also because it was not proven until recently that the body will spare its protein reserves and burn mainly fat during a fast; this makes fasting essentially safe for most people.

### **Why consider fasting?**

Because most people overeat, get too little exercise and rest, and are generally not mentally at peace, we get a build-up of toxins and waste material in the body. When a person fasts, the body will break down this material and either burn it for energy, or eliminate it. Also, during a fast, the body increases the level of repair activity, secures a complete rest, and rapidly loses weight.

### **Isn't it better to go on a juice diet than fast totally?**

No, water fasting (going on water alone) is far superior to juice dieting. For one thing, the elimination of salt from the body which occurs so rapidly while fasting and results in health improvement will not occur at all while on juices. Don't think of juice dieting as fasting. While on juices, a person ingests large amounts of calories, vitamins, minerals, and other nutrients.

### **Can every disease be "cured" by fasting?**

No. Remember, fasting is not a "cure." Fasting only provides the optimal condition for self-repair. This process of self-repair has its limitations also, depending on the case.

[Home](#) > [Lesson 45 - Introduction To Fasting](#) > Article #1: Living Without Eating by Dr. Herbert M. Shelton

## **Article #1: Living Without Eating by Dr. Herbert M. Shelton**

In March, 1963, newspapers around the world described the almost incredible story of the seven weeks deprivation of food and the survival of Ralph Flores, a forty-two-year-old pilot of San Bruno, California, and twenty-one-year-old Helen Klaben, a co-ed of Brooklyn, New York, following a plane crash on a mountain side in Northern British Columbia. The couple was rescued March 25, 1963, after forty-nine days in the wilderness in the dead of winter, over thirty days of this time without any food at all.

By means of a fire, a lean-to and heavy clothes in which they wrapped themselves, they managed to withstand the bitter cold. During the first four days after the crash, Helen Klaben ate four tins of sardines, two tins of fruit, and some crackers. Twenty days after the crash, the pair took their last "food"—two tubes of toothpaste. Melted snow became their diet, for breakfast, lunch, and the evening meal. "For the last six weeks," she explained, "we lived on water. We drank it three ways: hot, cold and boiled." Varying it in this way helped reduce the monotony of their single item menu of snow.

Miss Klaben who was "pleasing plump" at the time of the plane crash, was happily surprised, at the ordeal's end, to learn that her weight loss totalled thirty pounds.

Flores, who was more active during their enforced fast, had lost forty pounds. Physicians who examined them after the rescue, found them to be in "remarkably good" condition.

Many thousands of men and women have gone without food for much longer periods, not only without harm, but with positive benefits. Periods of abstinence under such taxing conditions as the ones these two people endured and survived are extremely rare.

One of Sweden's distinguished biochemists, Dr. Ragnar Berg, a Nobel Prize winner and an authority on nutrition, says, "One can fast a long time, we know of fasts of over a hundred days duration, so we have no need of fearing that we will die of hunger."

The actual time period of abstinence forced upon Mr. Flores and Miss Klaben was of relatively moderate duration. The question is not how long man can fast, but what are the provisions of nature that enable him to do so.

Wear and waste, repair and replenishment, are continuous and almost simultaneous processes in all living structures, and none of these processes halt during a fast. The hibernating animal in the far north must produce sufficient heat to maintain body warmth. Both man and animal, while fasting, must breathe and the heart must continue to pulsate. The blood must continue to flow and the organs of elimination must continue their work of freeing the tissues of waste. The vital functions of life must be carried on, even if at a slightly reduced rate. Cells must be replenished, wounds must be healed. All of this, as I know from years of observations, goes on during a fast.

All manifestations of life—movement, secretion, digestion, and similar processes—depend upon the use of the materials of the body. If an organ is to work, it must be supplied with the materials with which to work. In the absence of fresh supplies with which to replace those that have been used up, the organ wastes and weakens. If life is to continue, a basic irreducible level of activity is imperative. Even the hibernating animal, with activities reduced to a bare minimum consistent with continued life, must

breathe and the heart must pulsate.

An understanding of the process by which the body nourishes its vital tissues and sustains its essential functions during prolonged abstinence, and the sources upon which it draws, will help us understand how the body can survive periods when outside food is not available or cannot be digested.

The normal body provides itself with a store of nutritive materials that are put away in the form of fat, bone marrow, glycogen, muscle juices, lacteal fluids, minerals and vitamins. Always the healthy body maintains in store adequate nutritive reserves to tide it over several days, weeks, or even over two or three months of lack of food. This remains true whether fasting is enforced, as in the case of a plane crash or of entombed miners, or is brought on by illness where one cannot swallow or digest food, or by free choice as in voluntary fasting to lose weight. When food is not taken, the body draws upon its reserves with which to nourish its functioning tissues. As this reserve is used up, weight is lost.

Basic in the fasting process is the fact that our "built-in pantries" contain sufficient nutriment to hold out, in most instances, for prolonged periods, especially if they are conserved and not wasted. In the blood and lymph, in the bones and especially in the marrow of the bones, in the fat of the body, in the liver and other glands and even in the individual cells that make up the body, are stores of protein, fat, sugar, minerals, and vitamins which may be drawn upon during periods of scarcity or when food is not usable.

Neither animal nor man can survive prolonged abstinence from food unless he carries within himself a store of reserve food on which the body can call in emergencies. The fasting organism will not be harmed by abstinence so long as the stored reserves are adequate to meet the nutritive requirements of its functioning tissues. Even thin individuals carry a reserve of food in their tissues, to tide them over periods of abstinence. These people too, may safely fast for varying periods.

By a process known technically as autolysis, achieved by enzymes in the tissues, these stored reserves are made available for use by the vital tissues to which they are carried by the blood and lymph as required. Glycogen or animal starch stored in the liver is converted to sugar and distributed, as needed, to the tissues. It is significant that, even in prolonged fasts, no beriberi, pellagra, rickets, scurvy or other "deficiency disease" ever develops, thus showing that the reserves of the body are generally well balanced.

Fasting has been shown to improve rickets and calcium metabolism. In anemia, the number of red blood cells are increased during a fast. I have observed benefits in pellagra during a fast. The biochemical balance may be maintained and even restored while fasting. It is important to know this, for if it were not so, the fast would prove to be deleterious.

Numerous animal experiments have shown that underfeeding, as contrasted with overfeeding, tends to prolong life and to provide for better health. Other experiments involving fasting rather than underfeeding, have shown that fasting not only prolongs life, but results in a marked degree of regeneration and rejuvenation.

Thousands of observations of both man and animals have established the fact that when the physical organism goes without food, the tissues are called upon in the inverse order of their importance to the organism. Thus fat is the first tissue to go. The stored reserves are used up before any of the functioning tissues of the body are called upon to supply nutrients for the more vital tissues such as the brain and nerves or the heart and lungs. As it feels among its supplies for proteins, sugars, fats, minerals, and vitamins, and redistributes, utilizes, and conserves these stores, the fasting organism exercises an ingenuity that seems almost superhuman.

The aggregate of tissues of the organism may be regarded as a reservoir of nutriment which it may call in any direction or to any part as needed. But these tissues are not sacrificed indiscriminately. On the contrary, wastage of those organs that are primarily essential to life is repaired by withdrawal from less essential organs of materials required by the more important ones. Many of the necessary nutritive constituents, and this is especially true of certain minerals, are vigorously retained.

Studies made on men and animals to determine losses of various tissues and organs in prolonged abstinence from food have almost all been made on organisms that have died of starvation. Starvation and fasting are two totally different stages of abstinence. It should be quite obvious that the extreme losses seen at the starvation stage of abstinence are far greater than they are in a fast of reasonable length. Extreme weight losses are not experienced in any normal fast. Where they occur, the fast should be broken.

One must differentiate between fasting and starving. To fast is to abstain from food while one possesses adequate reserves to nourish his vital tissues; to starve is to abstain from food after his reserves have been exhausted so that vital tissues are sacrificed. We are not left unwarned as to when the reserves are nearing exhaustion. Hunger returns with an intensity that drives one to seek food, although during the fast proper, there is no desire for food. This differentiation between fasting and starving should help to dispel any notion that starvation sets in with the omission of the first meal.

Contrary to popular and even professional opinion, the vital tissues of a fasting organism, those tissues doing the actual work of life, do not begin to break down the instant a fast is instituted. The fasting body does lose weight, but this loss, for an extended period, is one of reserves and not of organized tissues.

The efficiency of the living organism in regulating the expenditure of its resources during a fast is one of the marvels of life.

In periods of abstinence, the less important organs of the human being, although they waste consequent upon the withdrawal of substance from them with which to nourish the more vital tissues, do not undergo degeneration until the starvation phase of the period of abstinence is reached. The atrophy of muscles may be no greater than that seen to occur from a lengthy period of physical inactivity, while there is no loss of muscle cells. The cells grow smaller and the fat is removed from the muscles, but the muscle retains its integrity and a surprising amount of strength.

Loss of weight varies according to the character and quality of the tissues of the individual, the amount of physical and emotional activity engaged in, and the temperature surrounding the faster. Physical activity, emotional stress, and cold and poor tissues all provide for more rapid loss. Fat is lost faster than any of the other tissues of the body.

Bodily condition is, perhaps, the chief determiner of how long one may safely fast. In the case of the two who survived the plane crash, and went four weeks without food, for example, they had snow which is water and this kept them from the danger of dehydration. They could live without food; the lack of water would have been fatal. Voluntary or involuntary, the faster must have water.

It is clear then that fasting must be carried out intelligently, with proper precaution, and with common sense.

Precisely as a novice swimmer would seek expert guidance and advice before starting on a long swim, so the inexperienced faster must obtain reliable guidance as a precautionary measure before launching upon a fast of any extended duration.

## **Article #2: Fasting In Nature by Dr. Alec Burton**

When we closely examine the animal world we discover that fasting is almost as common as feeding.

But aside from fasting per se there are two similar conditions which are related to our subject. They are hibernation and aestivation.

It is a universal verity that animals have some means of adaptation to food scarcity. Obvious examples of this are squirrels storing nuts, bees, storing honey, chipmunks storing roots and nuts, beavers storing twigs, and finally other animals capable of storing significant food reserves within themselves. These are the animals which hibernate. They undergo a period of winter sleep. Their metabolism is slowed down and they take no food for long periods of time. Bats, mice, hedgehogs, woodchucks, toads, lizards, snakes, flies, wasps, bees, bears, crocodiles, and alligators are among those that undergo some degree of hibernation. True hibernation is a dormant state of existence accompanied by great diminution of respiration, circulation, and metabolism. At this time, the animals' functions are almost suspended. Body heat is little. Action of the heart is almost imperceptible, and as much as 40% of the animal's total weight may be exhausted by the time it recommences feeding.

True hibernation is restricted to only a few animals: hedgehog, doormouse, marmot, and bat. This is a state where most of the essential vital functions continue at a very low level or degree. They are referred to by biologists as "imperfectly warm blooded types," which are unable to produce enough heat to make good their losses in cold weather. It is probable that the biologists' conception is inaccurate because in a number of species it is only the female that hibernates, which would suggest that it is food scarcity rather than temperature that precipitates hibernation.

Conversely, aestivation is a similar process which occurs in the summer time, and quite obviously these are not cold blooded animals. An example is the tenree of Madagascar. This climatic dormancy requires that the organism makes a variety of gradual physiological and biochemical adjustments that apparently correlate with temperature, light, and food scarcity.

Different hibernators adapt to different sets of conditions. Some store food, others do not. Some accumulate a great deal of fat and food reserves, others do not. However, there is a general preparation for the period of hibernation. An increase in fat deposition and adjustments of body temperature or what appears to be a "resetting" of the body thermostat are common. Metabolism adjusts, the heart and cardiovascular system show generally lower levels of activity.

A number of biochemical changes associated with the nutritional adaptation are evident. There is an increase of the element magnesium in the blood and the endocrine glands reduce their activity. This is especially so of the gonads. It is generally agreed among experts and observers that hibernation follows normal sleep. In other words the state is entered via sleep.

If, however, hibernation is to be looked upon as a type of sleep, it is an extremely complex one. But one factor which is dominant is energy conservation. All the adapted devices conserve the energy of the organism concerned.

One extremely interesting feature of hibernation which is of particular interest to us in our studies of fasting is the apparent improvement of health experienced by hibernating animals. According to observers, they do not develop "infectious" diseases. They are said "to have a greater resistance to disease," or at least some of its causes. It is claimed that the host's defensive mechanisms against parasites and their proliferation is substantially increased, it has also been demonstrated that the hibernating organism is more resistant to radiation and especially are the tissues rejuvenated and more capable of healing following the period of hibernation. Hibernation is in many ways an important survival mechanism.

As I mentioned earlier, hibernation and aestivation are interesting examples in our quest for understanding the biology of fasting; but as it is not possible for man to significantly reduce his physiological and metabolic processes, we cannot extrapolate from the lower mammals to man knowledge which is gained in this way.

It need hardly be said that the living organism requires materials with which to work. It requires nutrients to fuel its biological processes. It requires nutrients as a source of energy and to provide the

needed materials for the repair of wear and tear, for healing or regeneration, and for reproduction. It also requires a variety of other essential substances, minerals and vitamins, which are necessary for the regulation of the body's processes. Simply stated, it is not possible for an organism to survive without nutrients.

Professor Morgulis states that during a fast, an organism is living off the fat of the land. The Gila monster, a large lizard of the southwestern desert in Mexico, in fact a poisonous reptile, has a conspicuously large heavy tail. This is a source of nutrients in times of food scarcity and it is well known that the lizard is capable of going for extended periods of time without food. In one observation, one fasted in excess of two months.

It is commonly thought by people that the camel, having a large hump, is capable of travelling long distances without water. It is more true that the camel is capable because of its hump of going for long periods of time without food. The fat-tail sheep of Iran has an enormous reserve of nutrients available to it during times of scarcity. During periods of abundance, it stores food in the tail which is utilized when scarcity prevails.

As we would expect, there are many and diverse differences among the different species of animals so far as fasting and stored food reserves are concerned.

As we have seen, some animals hibernate—they are inactive for long periods, perhaps six or seven months. Conversely, there are animals that engage in vigorous physical activity while fasting. The Alaskan fur seal bull and the salmon are common examples. The fur seal engages in tremendous and relentless sexual activity over a period of twenty to thirty days during which it takes no food. During their long upstream swim salmon do not take food. It is also claimed that whales are capable of abstaining from food for long periods of time.

Professor Morgulis states in his book, *Fasting and Under Nutrition* that "active growth and regeneration are not incompatible with inanition and the wear and tear at least in some organisms is so completely repaired as to evade for a long time the effect of nutritional stringency. Inanition does not preclude the ability for extreme and sustained exertion."

It should be stressed that so far as our own discussion is concerned, we are advocating fasting as a means of physiological rest and this should be associated with physical, mental, emotional, and sensory rest so far as practicable.

One of the most unusual and fascinating examples of fasting is that it takes place during metamorphosis which represents a complete change of form during the life of an insect or other living creature. A good example of this is the tadpole during its period of transformation to a frog. It does not shed its tail, the tail contains nutrients; proteins, carbohydrates, fats, minerals, and vitamins. It is a source of nourishment for the changing organism.

We observe the process of "autolysis" which is the breakdown of stored nutritional reserves by the inter and intracellular enzymes. The nutrients are not usable as glycogen, fat, protein, etc. They must first be digested inside and thus supply the changing organism with basic materials to develop its new form. We will observe in this that the process of "autolysis" is a rigidly controlled series of events. The developing frog does not suddenly lose one of its newly formed legs or part of an eye. It only breaks down the needless tail.

Another example of this important biological process, which in life is going on all the time, is the common aspect of healing with the absorption of a ring of calus, which temporarily supports a fracture, when a bone has sustained an injury. By this remarkable process, this supporting ring is slowly removed. We see evidence of the same thing where congestive deposits surround a lesion, cut, or surface on the body—how these are rapidly broken down and removed. There are literally thousands of examples of fasting in nature, and it is indeed almost as common as feeding.

[Home](#) > [Lesson 46 - When To Employ Fasting; Determining Who Should Fast; How Long And How Often](#) > Part I: When To Fast

### **Part I: When To Fast**

Regarding the proper time to fast, Dr. Shelton maintained that the time to fast is "when it is needed." He states, "I am of the decided opinion that delay pays no dividends; that, due to the fact that the progressive development of pathological changes in the structures of the body with the consequent impairment of its functions does not cease until its cause has been completely and thoroughly removed. Putting off the time for a fast only invites added troubles and makes a longer fast necessary, if indeed, it does not make the fast futile. I do not believe that any condition of impaired health should be tolerated and permitted to become greater. Now is the time to begin the work of restoring good health; not next week, next summer, or next year."

So it is agreed that, when needed, fasting should begin as soon as possible. But how do you determine when fasting is needed? There will be definite indications that will manifest themselves, and at this point, there will be no question that a fast is required.

#### **1. Absence Of Hunger**

We can assume that when there is no hunger, there is also no physiological need for food. Hunger will be absent when: (1) there is no need for food, such as soon after a meal, and (2) when there is an inability to digest and assimilate food, such as occurs during acute diseases (e.g., colds, flu, etc.). When hunger is absent, therefore, no food should be taken.

If food is taken when the body lacks the ability to digest, putrefaction or fermentation takes place. This will result in the liberation of toxic by-products from the decomposition within the stomach. Toxins thus liberated enter the blood and tissues and contribute to toxicosis.

Pain, fever, inflammation, and abdominal distress cause one to lose his normal desire for food. Under such conditions you should refrain from eating until hunger returns. In acute disease, hunger is not present because the vital energy of the body is diverted into other channels. Since all energies are directed toward healing and repair, there is none to spare to carry on digestive work. Blood is also diverted toward the parts requiring healing. Under these circumstances, digestion is completely suspended. Yet, food is often taken under medical advice. It is said that we "must eat in order to keep up our strength." In such cases, the food is often vomited or expelled through the digestive tract by means

of diarrhea. If not, the food becomes a burden adding to the poisoning of the body.

Even when these unwanted food materials are expelled from the body, precious vital energy is used up during the process. Forces are diverted from the work of repair and wastefully expended in an effort that could have easily been avoided by fasting. Recuperation is thus slowed.

In many cases, during acute and chronic diseases, a person may feel hungry. In reality, it is not hunger that he feels but a morbid craving for food. Hunger is often misinterpreted by a headache, irritability, restlessness, lassitude, drowsiness, faintness, a feeling of emptiness, gnawing pains in the stomach, etc. In fact, none of these symptoms indicate true hunger. Hunger is a normal, pleasant physiological demand for food that is felt in the mouth and throat as is thirst. Since it is a normal occurrence, it is not accompanied by pain or discomfort.

## 1.1 Hunger vs. Appetite

One simple method of determining true hunger is to think of how much time has elapsed since the last meal. If you desire to eat while the last meal is still digesting you are not hungry. If your last meal was a heavy one that included nuts or avocado, your next meal should not be for at least four to five hours.

Remember that genuine hunger is not associated with pain or discomfort. A healthy individual can easily miss a meal or two without feeling weak or experiencing pain. If he does, it is a sure sign that a fast is indicated, followed by a change in eating habits.

People who feel faint or experience headaches upon missing a meal are going through "withdrawal symptoms" from the addictive substances that they ingest with their foods. The more one is addicted to salt, condiments, coffee, tea, etc., the more severe the symptoms. The quickest, surest, and safest method of ridding yourself of these addictions is through a fast. Dr. Susanna W. Dodds stated that "the sense of all-goneness in these cases is not from a lack of nutrient material, but owing to the absence of the habitual stimulus."

The hunger of the poorly-nourished individual (one who consumes processed foods such as refined sugar and flour; cooked foods; meat; etc.) is of the same nature as the drug addict who is deprived of his drug. They experience such symptoms as gastric distress, pains in the stomach region, a gnawing in the stomach, weakness, headache, etc.

On the contrary, normal muscular contractions are not painful, they tend to be pleasurable. Hunger is not a pathological state and is not manifested by symptoms of disease.

Dr. Shelton says, "The truly hungry person has no consciousness of his stomach and does not suffer any morbid symptoms. Indeed, genuine hunger is such a delightful sensation that it is worth going on a fast merely for the pleasure of experiencing it."

## 2. Fasting In Acute Disease

The rule of nature in acute disease is *go to bed, keep warm, and abstain from all food until hunger returns*. Fasting in fevers was commonly employed by Neapolitan physicians over one-hundred-and-fifty years ago. They frequently permitted their fever patients to go for as long as forty days without food. Dr. Shelton states, "When in pneumonia and pleurisy, the patient is fed, not only is the toxic saturation kept up, but feeding retards resolution; that is, it prevents the inflamed lungs and pleura from returning to normal."

When animals become sick, they instinctively refrain from eating. They remain quiet and rest until their appetite returns and at that time, it is a sure sign that they are recovered. The same requirements apply to man. That is, quiet, rest, and fasting, with a little water as demanded by thirst. But often, man refuses to allow himself to be guided by instinct as the animal does, and eats in spite of lack of hunger. By so doing, he weakens his body even more.

In all types of acute diseases, the whole organism is occupied in the task of eliminating toxins. It is perfectly natural that the body should rebel against food during this time. Such symptoms as anorexia, bad breath, coated tongue, nausea, vomiting, excretion of mucus, diarrhea, etc., indicates that the body is occupied in the work of elimination and is not able to digest food.

## 2.1 Feeding The Sick

During acute illnesses, it is often advised that meat broths be served. These broths *not* only do not contribute to health but produce the "soil" for disease. During my bacteriology classes at school, we often used meat medias to culture our bacteria. This media proved excellent for producing large colonies of various types of bacteria since the "soil" or "food" for these bacteria was close to ideal. While we know that bacteria do not cause disease, they are present in many disease conditions. When the "soil" is ideal for bacteria to proliferate, they will do so. This is an excellent indication of toxicosis due to the decomposition of food and bacteria in the stomach and digestive tract.

Since acute disease is an effort on the part of the body to rid itself of excess toxins, you should not interfere with or abort that effort by adding more toxins to the body by ingesting the exact food that resulted in excess toxins to accumulate in the first place. Actually, even the best foods are potential toxins during acute illnesses.

Dr. Shelton says that one of the rules for the sick is to stop the absorption of all toxins from the outside. He states, "Feeding during acute 'disease' does just the opposite. It keeps the digestive tract full of decaying animal and vegetable matter, which the body must void or absorb. Putrescence arising from gastro-intestinal decomposition, grafted onto the pre-existing enervation, toxemia and dyscrasis, form the cause of practically all the so-called 'diseases' from which man suffers."

During acute gastritis, the mucous membrane of the stomach is red and swollen. There is little gastric juice and very little acid excreted, with considerable amounts of mucus present. With the stomach in this condition, and with appetite lacking, it would be senseless to eat. Fasting in such a case is the only rational procedure. Without the irritating presence of food and its products of decomposition, the body will proceed to heal and health will be restored.

### 2.1.1 Peptic Ulcer

An example of feeding during disease is demonstrated in the peptic ulcer patient. Peptic ulcer is the general term given to an eroded mucosal lesion in the stomach or the duodenum. It is claimed that excessive excretion of hydrochloric acid is the cause of this condition. While this may be the irritating or immediate cause, the underlying reason the hydrochloric acid is secreted above normal is due to general enervation and toxicosis. The generally accepted dietary "therapy" involves a "bland" diet. This diet consists of exactly those foods that contributed to the general enervation and toxicosis in the first place. Foods often recommended include milk, eggs, cooked refined cereals, custard, Jell-O, ice cream, white bread, cheese, and creamed soups. These foodless "foods" do not contribute to health.

Complete abstinence from food is indicated in such cases to allow the body to heal without the irritation of food. This, is the quickest and surest manner to recover health. The strong "hunger pains" that are said to be felt by such patients are not true hunger.

Another example of feeding in disease is dietary therapy for such intestinal disease as diverticulosis and diverticulitis. Instead of searching for the underlying cause of this condition, physicians palliate symptoms and make matters worse. Dietary therapy in such cases would make any well man sick. It includes milk, coffee, tea, carbonated beverages, eggs, cheese, meat, soups, cooked strained vegetables, cooked strained fruits, white refined bread, refined cereals, white rice, macaroni, noodles, spaghetti, and other refined products. Man could live many times longer on water alone than he could on the diet described for diverticulosis. Any value found in the fruits and vegetables are cooked away, and straining and pureeing makes them worse. Again, a fast is indicated followed by correct eating habits and the

body will once again be restored to normal.

### **2.1.2 Pain**

Any pain that a person may experience is known to lessen while fasting. Dr. Shelton has witnessed many patients with pains of acute articular rheumatism subside and the patient became comfortable after three or four days of fasting.

## **3. Fasting In Chronic Disease**

The time to fast is before a disease becomes chronic. If a fast is undertaken when the symptoms of acute disease first manifest themselves and a more healthy lifestyle is adhered to, chronic diseases will not occur. What often happens, however, is that when symptoms of acute illnesses arise, they are suppressed by various drugs, etc. The body is never allowed to eliminate its toxic overloads that have accumulated over a period of time due to unhealthful living habits. Due to this constant suppression and continued bad habits, chronic diseases develop. At this point, many people turn to fasting as "a last resort."

In spite of all the abuses that the body has been put through previously, beneficial results occur through a fast at this time. One important feature about fasting in chronic diseases is the marked acceleration of eliminations that occurs. The body is thus speedily freed of its accumulated toxic load. Symptoms disappear that were sometimes of years standing. In this regard, Dr. Shelton says, "A properly conducted fast will enable the chronically ill body to excrete the toxic load that is responsible for the trouble, after which a corrected mode of living enables the individual to evolve into a vigorous state of health."

Fasting has been instrumental in bringing about the recovery of persons suffering from asthma, arthritis, diabetes, various tumors, heart disorders, and numerous other diseases. Why was fasting so effective in all of these diverse diseases? The reason is that the diseases may differ as to the symptoms that they manifest but the underlying causes remain the same. Two people practice bad habits for years, one of them being about as indulgent as the other, and one of them develops asthma, the other develops arthritis. Health may be restored in each case by the same means—fasting.

Dr. Shelton cites a case of a young singer who had developed a serious asthmatic condition and could no longer sing. The doctor gave her no hope and told her that there was no "cure" for asthma. She finally had to give up singing, and she retired to her farm. Then she heard about Natural Hygiene and the concept of the importance of the body's own healing capacity. She decided to give this system a chance. Upon consulting with Dr. Shelton, she decided to fast. In a matter of weeks, the asthma cleared; and within a few months, she was back singing. Her career had been saved and so was her health. Keep in mind, however, that fasting did not do anything, but provided the ideal conditions for the body to heal.

Another example of fasting in chronic disease is cited by Dr. Shelton. This case involved a man who had arthritis for twenty-eight years. Dr. Shelton describes the case:

"With the passage of the years, joint after joint became involved until the patient was a twisted and distorted man walking with the aid of crutch and cane, in a much stooped position. He was unable to turn his head from side to side, and he was in constant pain.

"He was told that there was a possibility that some of his joints would remain ankylosed. There is no way to unfuse ankylosed joints. They remain fixed, immovable. The good news was, in this case, however, that he could be freed of pain. He could be restored to usefulness and he could enjoy life.

"This man underwent a lengthy fast—one of thirty-six days. There was great improvement. He was freed of pain, witnessed the disappearance of swelling from some of his joints, its reduction in others, and the slow return of movements to joints that had long been stiff.

"It took four years to complete all the improvements possible in this man. During this time, he had a second long fast and several fasts of a few days each. His eating between fasts was carefully supervised. He was given daily sun baths; and after a certain amount of initial improvement had been made, he was

given daily exercise.

"Result: his spine is almost straight, the use of his arms and legs is normal, he can turn his head, he walks in a nearly upright position, he does not use cane or crutch, he has no pain, he looks the 'picture of health,' and he works like a slave."

This case was an extreme one requiring a lengthy period for recovery but it serves to illustrate what the body can accomplish when given the proper conditions.

#### **4. Fasting To Lose Weight**

Dr. Dewey said, "There are no overweights who would not receive the greatest benefit by a fast that would diminish the pounds to that of the ripest maturity of life, a fast that would be determined by the time required to reach the desired number of pounds."

Fasting is not only a quick, safe, and effective way to lose weight but the added benefit of ridding the body of toxic debris is a bonus. Fasting will help the obese individual overcome his food addictions to sugar, caffeine, and junk food, and make a smooth transition to a more healthful way of eating.

When the overweight individual undergoes a marked reduction of weight during a fast, general improved health is indicated by freer breathing, greater ease of movement, increase of energy, cessation of symptoms of indigestion and other discomforts, lowered blood pressure, and lessening of the load the heart has to carry.

On the average, the individual loses about two-and-one half pounds a day on a fast. Since hunger is almost always absent during this fast, it is a much more pleasant way to lose weight than the popular reducing diets. These diets often include unwholesome foods, and weight loss is often minimal. The dieter soon becomes discouraged and once again indulges in his former manner of eating. If weight loss is obtained through such a diet, it often results in flabbiness or sagging of the skin and tissues. This does not usually occur during the fast. So fasting is rapid and fast, more pleasant than reducing diets, and no flabbiness or sagging of the skin results.

People often ask how much weight loss per day is safe in fasting? Dr. Shelton says that the body itself decides what rate of loss is proper. When fat tissue is soft and flabby, weight is usually lost rapidly in the early days of the fast. In other individuals, the rate of loss may be considerably slower, but the end result will be the same. That is, total weight reduction and improved overall health.

#### **5. Drug Addictions**

Any form of drug addiction is a foolish attempt to obtain relief from headaches, nervousness, irritability, and other symptoms through suppression. The craving for these drugs inevitably leads to enervation of the nervous system. Addicts will take their coffee, alcohol, tobacco, etc., to "calm their nerves" and they feel faint and weak without them. This is an illusion. The drug effect makes them unaware of their true condition. These poisons do not make them stronger but result in more weakness and enervation. It is not the drug that forms the habit but it is man. And it is he who must suffer the consequences from his unwise habits.

Nothing enables the drug addict to overcome his false "need" for his poisons better than does the fast. Few drug addicts have sufficient willpower or physical strength to overcome their addictions without help, and the fast will provide such assistance. These people will be able to abandon their former habits and their overall health will be markedly improved.

##### **5.1 Alcoholism**

The alcohol habit progresses slowly until it reaches a chronic stage. During this progression, all bodily systems have become enervated and damaged to a certain extent. The alcoholic is a chronically-sick

individual. With this in mind we can readily see why fasting is of great benefit in this case. During this period of rest, the abused organism undergoes healing and repair and eventually regains its wasted vital energies. By the end of the fast, the body will have eliminated its accumulated toxins and the nervous system will be restored to health (as far as there was no permanent damage).

Alcoholism is an illness involving structural abnormalities. It has been found that alcohol causes damage to all tissues where it comes into contact. As a person drinks a glass of alcohol, it causes damage to the esophagus by direct chemical irritation to its mucosa, by inducing severe vomiting that tears the mucosa, or by interfering with normal motor functions thereby causing an upward movement of the stomach acid into the esophagus where it can erode the tissues.

As the alcohol passes into the stomach, it includes inflammation and bleeding lesions of the stomach. The degree of the damage it causes to the stomach lining appears to be related to alcohol concentration, with damage to the cells occurring rapidly after alcohol ingestion. In the small intestine, the impeding peristaltic waves are decreased by alcohol and propulsive waves are unchanged, resulting in an increased rate of propulsion through the small intestine. This effect is seen as a possible contributing factor to the diarrhea frequently experienced by binge-drinking alcoholics. Intestinal malabsorption may also result from alcohol ingestion.

As alcohol passes through the liver, it inhibits the conversion of amino acids to glucose. Alcohol can also stimulate hepatic synthesis of certain other proteins, including lipoproteins that transport fats in the blood. This effect may explain the elevated blood triglyceride (fat) levels frequently seen after alcohol ingestion. The alteration in fat metabolism may result in a gradual accumulation of fat in the liver and a "fatty liver." This condition can result in the liver failure and death. Alcoholic hepatitis is a major effect of heavy chronic alcohol consumption and may be a precursor stage of cirrhosis. Cirrhosis is a chronic inflammatory disease of the liver where functioning liver cells are replaced by scar tissue.

Alcohol has adverse effects on the nervous system. Brain nerve cells generate and conduct electricity, transmitting information to an adjacent nerve cell by the release of specific chemicals called neurotransmitters. The receiving cell provides feedback to the transmitting cell regarding the message sent. Each cell can receive and integrate information from many others, a function that alcohol can alter.

Electrical currents in nerves are transmitted from the membrane of the nerve cells to the inner cell. This mechanism is closed when the resistance of the cell membrane is reduced at any point, resulting in electrical changes carried by sodium and potassium ions flowing across the membrane in a movement called the action potential. Alcohol impairs the opening of the mechanism, so the nerve has difficulty refiring. Neurophysiologic studies have shown that ethanol inhibits the sodium current in the action potential.

Alcohol consumption results in heart enlargement, abnormal heart signs, edema, enlargement of the spleen or liver, noisy breathing, electrocardiographic abnormalities, and disturbances of cardiac rhythm and conduction.

Dr. Dewey maintained that the alcoholic can only recover his health through a fast. He says, "Only through a fast that shall let that distressed stomach become new from regeneration, that will let the brain accumulate rest in reserve."

When the alcoholic fasts, the tissues of the stomach, intestines, liver, heart, nerves, etc., begin to repair themselves and healing takes place. Glands and nerves that have been so enervated by overstimulation are allowed to rest. Nerve energy is restored; and by the end of the fast, the former alcoholic feels stronger and more vital than ever before. He will no longer desire alcohol as Dr. Shelton explains:

"When the alcoholic has fully recovered from his illness and hunger has returned, no form of alcoholic drink will tempt him and should he attempt to drink some form, he will discover that he no longer 'likes' it. It will *bite* and *sling* as it did when he first took it as a youth. He will be a free man again—no longer a slave to King Alcohol."

## 5.2 Tobacco

The use of tobacco results in symptoms of irritability, grouchiness, nervousness, and uneasiness. The user of tobacco may repeatedly try to discontinue this habit but fails and returns to his poison to supposedly sooth those same symptoms that were first induced by the tobacco. He lacks the willpower and determination to stick it out until the nerves have repaired themselves.

Fasting is extremely useful in these cases. It makes the discontinuing of the tobacco habit very easy, and in a few days, the very taste of this substance becomes repulsive. Dr. Shelton says, "I have seen heavy smokers who smoked half a lifetime, after a fast, become so 'sensitive' to the obnoxious fumes of tobacco that the odor of a cigar wafted to their nostrils from a block away was objectionable to them."

## 5.3 Other Drugs

In all other drug addictions (such as marijuana, cocaine, heroin, etc.) rest—physical, mental, and physiological—is the greatest need. After a short time, the craving for these poisons will diminish and soon disappear. The gradual tapering-off process that is often resorted to for drug addicts is not a wise procedure as this process continues to injure, and no real benefits are gained.

At the very onset of the fast, often violent withdrawal reactions take place. It is recommended that these fasts take place under the direct supervision of one who is experienced in fasting. These withdrawal reactions soon cease as the patient continues the fast. The body will then proceed to repair the damage that was done by the drugs, and toxins will be eliminated. Of the many cases that Dr. Shelton has observed at his Health School, he states that none have ever returned to their former drug use.

[Home](#) > [Lesson 46 - When To Employ Fasting; Determining Who Should Fast; How Long And How Often](#) > Part II: Determining Who Should Fast

### Part II: Determining Who Should Fast

Dr. Shelton says, "There, is hardly a time of life or a condition of body in which a fast cannot be helpful." There are some individuals who should only fast under supervision, but, in general, everyone can be benefitted by an occasional fast. You do not have to be acutely sick or suffering from some chronic ailment to profit from a fast. This physiological rest provides an opportunity for the body to restore vital energy that cannot be accomplished as well by rest alone. When the body is greatly fatigued, there is reduced ability to digest food. It would be unwise to eat under such circumstances. Rest is needed. When the body has regained vitality and hunger returns, the fast should be broken.

To eat a certain number of calories or a certain amount of high-grade protein will not insure health if the body is unable to properly digest and assimilate it. You may eat the best of organically-grown food but if the body is exhausted or under emotional stress, the food will ferment, and instead of contributing to health, there will be an opposite effect. Toxicosis will result from the decomposition of these foods. The proper response, under these circumstances, would be to fast until such foods can be digested.

Dr. Shelton states, "Our golden rule in eating has long been: *if not comfortable in mind and body from one meal to the next, miss the meal*. If the healthy individual overeats, eats under states of fatigue or excitement so that discomfort follows the meal, it is well to miss the next meal. If there is worry, fear, anxiety, grief, inner conflict, or other emotional stress, miss one or more meals."

## 1. Fasting For Children

Children often instinctively know when to fast and for how long. When the child refuses food, it is best to leave him alone until natural hunger presents itself, and he will demand food at that time. Children will lack all desire for food when they are ill. When they are enervated and toxicosis presents itself in the symptoms of gastritis, enlarged tonsils, constipation, diarrhea, gastritis, feverishness, etc., there will be no demand for food. Under such circumstances, the child should be allowed to fast until all symptoms disappear and hunger returns. These children should never be forced to eat as food will decompose in the stomach and its toxins will just make matters worse.

In dealing with the child, competent Hygienic guidance should be sought and followed. Sometimes a child may request food even though he is suffering from a cold or flu, but food should not be given until all symptoms have subsided.

Dr. Emmet Densmore says, "It is frequently, perhaps usually, said of this or that or the other baby that it is fretful or peevish. It is fretful because it is ill, and it is ill usually because of improper feeding. The same error that adult human beings make in regard to themselves is made in regard to the feeding of children—they are fed too often and too much."

Infants may suffer from indigestion due to excessive handling, overfeeding, or eating candy and other unwholesome foods. One of the first signs of such indigestion is noticed by white specks in the bowel movements. This indicates that the milk is not being digested. It is often wise to skip a feeding or two at this point. If the condition is corrected at this point, no other adverse consequences will develop and health will be restored promptly. If not corrected, inflammation of the stomach, small intestine, and large intestine may develop.

It is also important that the infants and children be properly fed after the fast. A diet of fresh raw fruits, vegetables, and nuts is proper for the child. Mother's milk is ideal for the young infant followed later by freshly-made fruit juices or fruit purees made from fresh raw fruits.

Regarding the proper food for infants and children. Dr. Densmore says, "Cereal or grain and all starch foods are unwholesome for all human beings; but this diet is especially unfavorable for children, and more especially for babies. The intestinal ferments which are required for the digestion of starch foods are not secreted until the infant is about a year old; and these ferments are not as vigorous as in adults for some years. All starch foods depend upon these intestinal ferments (enzymes) for digestion, whereas dates, figs, etc., are more nourishing than bread and cereals, and are easily digested—the larger proportion of the nourishment from such fruits being ready for absorption and assimilation as soon as eaten."

Concerning fasting in children Dr. Shelton states, "...while always acting under proper Hygienic direction with your child, do all that you can to let the natural tools of rest, and peace and quiet restore the child if there is upset or illness—or even if it is only a question of how much he wants to eat.

"For there are ways in which the instinctive wisdom of the infant or child in such matters may be far greater than we could possibly guess."

## 2. Fasting In Pregnancy

Pregnancy is a normal biological process that should not be accompanied by pain, discomfort, or any abnormal condition. In their natural state, animals do not suffer with nausea and vomiting during pregnancy. Primitive women are said to experience no sickness during pregnancy. This indicates that "morning sickness" and vomiting are not normal developments during pregnancy. If a woman suffers nausea and vomiting, it is not due to the pregnancy but to the toxicosis that was developed over a period of time before her pregnancy.

The body attempts to provide the ideal conditions for the developing fetus. It therefore goes about a "house-cleaning" to eliminate toxins that would make these conditions less than perfect. Many changes

take place in a woman's body during pregnancy. Glands long dormant awaken to activity. Her whole body undergoes a strengthening, renovating process. If a woman has been living healthfully, there will be no trace of unpleasant symptoms. If renovating work is needed, then a fast is called for.

A few days' fast (longer fasts should not be undertaken during pregnancy) will enable the body to rid itself of toxins and thereby provide suitable surroundings for the fetus. After the fast, if a healthful lifestyle is led, health will be kept throughout pregnancy.

### 3. Who Should Not Fast

As Dr. Shelton points out, the dangers of fasting are so slight they are almost negligible or insignificant. He lists several contraindications to fasting that are often made.

1. Fear of the fast on the part of the patient—It is best to educate the patient of the purpose of the fast and what to expect during the fast. Let him do some reading about the fast and about other people's experiences. Once his fears are alleviated, a fast can commence. Also, the fast itself often dispels such fears.
2. Extreme emaciation—People who are extremely emaciated may go on short fasts with definite benefits. When such people do fast, it is wise to keep the fasts short, and this may mean breaking it before hunger returns. But with proper living between fasts these people can be restored to health. Dr. Shelton feels that it is only through the fast that such individuals can be restored to health.
3. In cases of extreme weakness or of extreme degeneration—Even in these cases short fasts often prove to be extremely beneficial but they should be supervised. In the later stages of cancer, even a long fast will not result in health, but may perhaps relieve some discomfort or lengthen life for a few more days. Weakness itself is not a contraindication for fasting but is a sign that the body is in a state of toxicosis and is ready for an eliminative crisis. In this case, supervised fasting is very beneficial. Persons with heart disease have been known to make full recoveries following a fast but close supervision is again required.
4. In cases of inactive kidneys accompanied by obesity—It is said that in such cases, the tissues may be broken down faster than the kidneys are able to eliminate them. Dr. Shelton has fasted obese individuals with inactive kidneys with successful results. Most often the kidneys are enervated due to high-protein diets and other dietary abuses and a rest is exactly what is needed. The rate of tissue breakdown is not more than the body can deal with.
5. Difficult breathing—If the breathing difficulty is due to heart impairment, the fast should be closely watched and if the heart shows signs of weakening, the fast should be broken. However, Dr. Shelton says that he has fasted many such cases with beneficial results.

### 4. Fasting In Deficiencies

Most so-called deficiency diseases are not due so much to lack of essential nutrients as they are due to inability to *absorb* and *utilize* those nutrients. Fasting will enable the body to eliminate toxins, restore vital energy, and readjust and realign itself so that all available nutrients can be efficiently utilized. If a healthful diet is eaten after the fast, no deficiencies will arise.

In fact, certain vitamin and mineral deficiencies have been known to correct themselves during the fast while no food is being taken. The body will normalize itself during the fast and utilize stored nutrients.

## Part III: How Long, How Often

### 1. Fasting Vs. Starving

There is a difference between fasting and starvation. Starvation results from food being denied to a person whose reserves have been exhausted, and, in its extreme stages, leads to death. Fasting, on the other hand, is a period of rest and renewal with a potential for remarkable benefits with the body using its stored reserves as food.

We are not so much concerned with how long it will require a man to die from want of food, but how long he can safely and beneficially abstain from food. A little over three months are the longest fasts that have been recorded in man and these have been in overweight individuals. The man of moderate weight would not fast so long; and he would not need such an extended period of fasting. It has been said that a well-nourished adult can remain alive from fifty to sixty days without food, *provided, of course, that he has water*. Hundreds of longer fasts have been recorded and most of these have resulted in great benefit to the fasters.

### 2. Length Of The Fast Is Guided By Developments

The organism requires time to do its "housecleaning." If we were to arbitrarily set a time limit for this important work, we would stand in the way of recovery. The best way to determine the length of the fast is to be guided by the developments. It is not possible to know how long it will take a stomach ulcer to heal, or for an asthmatic to attain full recovery. Since it is not advisable to break the fast in advance of complete healing, you must be guided by certain signs.

When symptoms disappear, it is a favorable sign, but it still does not indicate that the fast is to be broken. One of the surest indications is a clear tongue, sweet breath, and return of hunger. This may occur after two days or two months or longer depending on the individual.

Occasionally, it is necessary to break the fast before these signs manifest themselves. A sudden fall in blood pressure; a rapid, feeble and irregular pulse; a disturbing dyspnea (difficult breathing) may indicate that the fast should be broken. The attitude of the patient and his emotional stability are factors that cannot be ignored. If the patient is unwilling to continue the fast or becomes excessively worried and anxious, the fast may have to be terminated.

Although it is always best to continue a fast until its natural termination, breaking the fast under such conditions will do no harm as long as proper feeding is carried out after the fast. After a while, a second fast may be undertaken with benefit.

#### 2.1 The Tongue and the Breath

Soon after entering upon a fast, the tongue coats heavily, and this coat may continue to increase as the fast progresses. This coating will persist during the fast up to a certain point when it begins to spontaneously clean itself up. As long as the body is actively eliminating toxins, the tongue will remain coated, but when this elimination begins to decrease, the tongue will clear up and remain clear. Dr. Hereward Carrington says, "A short while before the return of hunger, this cleansing process of the tongue commences and continues until the tongue is perfectly clean, assuming a beautiful pink-red shade—rarely or never seen in the average man or woman; and the terminus of this cleansing process of the tongue is absolutely coincidental with the return of hunger and of health."

Carrington stated that this coated condition of the tongue indicates the condition of the mucous

membrane throughout the alimentary canal since this membrane is so closely interrelated and connected. I would add that this foul condition of the tongue not only is an indication of the mucous membranes of the intestines but also of the health of the mucous membranes throughout the entire body.

If the fast is broken before the tongue clears, the tongue will become clean after eating has resumed. This indicates that elimination has been halted, but it does not necessarily mean that elimination has been completed. It is always best to fast until completion whenever possible.

The breath is also an indication of elimination of toxic debris. Although the breath may be somewhat foul before the fast, during the fast it becomes more so. This peculiar odor of the breath continues during the fast and only becomes sweet when the fast is ready to be broken after elimination has ceased. Dr. Carrington associates bad breath with elimination via the lungs. He says, "Precisely coincidental with the heavy coating of the tongue—following immediately upon the commencement of the fast—is the greatly increased foulness of the breath, showing unmistakably that the lungs are assisting in the speedy elimination of all corrupt matter from the system with the greatest possible speed."

The above two conditions serve as a unique and constant guide as to the condition of the fasting patient.

### **3. How Often**

As regards to how often to fast, we again must say, rely on instinct. When hunger disappears or acute symptoms appear, a fast is needed. It is important to understand that fasting is a tool that enables the body to redirect its healing powers where needed. It is not a "cure." You should not use fasting as a crutch to lean upon every time you choose to live unhealthfully between fasts. Fasting is but one part of an entire way of living that will maintain health. In between fasts, the other conditions for health should be adhered to. This includes proper food and water, exercise, sunshine and fresh air, rest and sleep, and emotional poise.

[Home](#) > [Lesson 46 - When To Employ Fasting; Determining Who Should Fast; How Long And How Often](#) > Questions & Answers

## **Questions & Answers**

### **Does everyone undergo violent crises during the fast?**

Disagreeable crises only occur in a small percentage of cases. Everyone can fast for a few days without inconvenience. According to Dr. Shelton, most fasters go through even a long fast with nothing more dramatic developing than they experienced during the regular activities of life. Most of the work of excretion is carried on silently and without the production of troublesome crises. In the human body, it is the task of the excretory organs to expel all waste and all foreign material that may find their way into it. They continue to do this, usually with greater efficiency, during the fast.

### **Can older people fast?**

The older person can fast with beneficial results if done under supervision. Dr. Shelton has conducted numerous fasts in both men and women whose ages ranged from sixty-five to eighty-five. Many of these patients had long fasts from thirty to over forty days.

### **Could you review the basic rationale of fasting?**

Dr. Shelton outlined four important facts about fasting; he says:

1. Fasting, as a period of physiological rest, affords the tissues and organs of the body an opportunity to repair, renew, and replenish themselves. Damaged organs are repaired; worn out and diseased cells are discarded and cast out.
2. Fasting, as a period of physiological rest, affords an opportunity for recuperation of depleted energy.
3. Fasting, because it compels the body to rely upon its internal resources, forces the tearing down (by autolysis) of growths, effusions, infiltrations, deposits, accumulations and excesses. These are thoroughly overhauled, their usable constituents are employed in nourishing the vital tissues, their unusable portions are excreted.
4. Fasting, by the foregoing and related processes, enables the body to regenerate itself to a marked degree. It becomes younger in physiological condition. Its functions are improved, its structures repaired, and its fitness to live increased.

### **I have heard that fasting has a rejuvenating effect. Is this true?**

Yes, this is true. The body is constantly going through a process of regeneration. This daily renewal of cells and tissues delays old age and early death despite the abuses that are imposed upon the bodies of most people. Fasting enables the processes of renewal to out-distance the processes of degeneration and the result is a higher standard of health. Regeneration of the muscles, tissues, and bones is possible through this method. During the fast, we may actually tear down much of the body and then rebuild it and have a renewed one.

The rejuvenating effect upon the skin is visible to all. Lines, wrinkles, blotches, pimples, and discolorations disappear. The skin becomes more youthful, acquires a better color and a better texture. The eyes clear up and become brighter. One looks younger. The rejuvenation is also present throughout the entire body.

[Home](#) > [Lesson 46 - When To Employ Fasting; Determining Who Should Fast; How Long And How Often](#) > Article #1: When To Fast by Dr. Herbert M. Shelton

### **Article #1: When To Fast by Dr. Herbert M. Shelton**

Called the "hunger cure" by European nature curists and many early Hygienists, fasting has shown by "large experience," as Robert Walter, M.D., expresses it, "... that a moderate hunger-cure is exceedingly beneficial in the great majority of diseases. Indeed, in many of them the capacity to appropriate food is entirely destroyed, the very thought of it becoming repugnant to the individual."

"Rest and the hunger-cure," Walter regarded as the "proper treatment" of those who were suffering from overwork and overeating. He pointed out that when there was functional impairment, coated tongue, and bad breath, no food should be taken. When uncomfortable in any way, stop eating until feeling well, he advised.

Kittridge says, "If a person has a coated tongue, fetid breath, and bad taste in the mouth, you may be pretty sure it will do him good to fast—appetite or no appetite." Judgement is required, wrote Kittridge, to determine when to put a person who still has an "appetite" on a fast. "When they don't have a desire for food," he continues, "no sensible man will think of eating or giving others to eat."

It is a mistake to think that food is a daily need under all circumstances. To constantly feed an irritated stomach is like kicking a man when he is down. Constant tampering with the stomach when it is as much in need of rest as the remainder of the body is to invite disaster. It is no uncommon thing to find

sufferers whose disease is largely due to overfeeding by their physicians in an effort to affect a *cure*. We see people gradually dying of malnutrition—malassimilation, starvation—in spite of the fact that they are eating regularly. We see physicians urging invalids to eat, urging the eating of foods that should be excellent for a well person; yet the patient, doing all he can to comply with the physician's instructions continues to waste. He lacks power to digest the food. The physician needs to know that continued eating under such conditions can kill. If eating does not prevent sickness, how will more feeding restore health? How will overfeeding be helpful?

Fasting is useful only because of wrong life. It is better to live right than to turn into excesses, and then fast. It is also better to take a short fast early than to permit yourself to get into a condition in which a long fast is required. If a fast is taken at the first signs of disease, perhaps ten days will be adequate. If, after years of suffering and considerable loss of weight, a man may still safely fast for more than forty days, surely a shorter fast would have been well borne at the beginning.

Writing in *The Hygienist*, June 1912, Dr. R. R. Daniels of Denver, Colorado, gave an expression to a view that has been widely held and that is still held in certain circles. He said: "... the sick should fast only when the system is unable to care for food. ... Always in acute disease when fever is present, or when in the absence of fever the patient is suffering from shock. ... In illness without fever but in which the appetite is entirely lost or the organs of digestion are entirely disabled ... frequent disturbances of digestion or elimination due to overfeeding in which the appetite is entirely lost or the organs of digestion are entirely disabled ... frequent disturbances of digestion or elimination due to overfeeding in which the appetite is temporarily lost. ... Except for the occasional 'storms' attended by intense pain or other distress which inhibits digestion to the extent that it is impossible to take care of food, fasting is not the best treatment for chronic disease. While in chronic disease, the power to take care of food is always impaired, often badly impaired, nevertheless there are usually some foods which can be digested and utilized, and these should be given ... fasting should be used only when disease is present to the extent that digestion is suspended ..."

This view was shared by Dr. Henry Lindlahr (Chicago) of Nature Cure fame, who held that fasting should be employed only in acute disease and during the crises that arise in chronic disease. Many others have accepted this view of fasting, despite the fact that, even in those many thousands of cases of chronic disease that complain of a lack of desire for food, and that everything they eat causes suffering, there is present the power to digest some food. Dr. Daniels gave it as his opinion that in chronic disease "if the feeding is limited only to the foods which can be utilized, chronic disease can be eliminated more rapidly and the nutrition built up faster than by fasting."

Although frequently employing and advising the fast in conditions in which there is considerable digestive power, Tilden often expressed views that harmonized with the view of Daniels and Lindlahr. For example, he once wrote that, except under certain circumstances (circumstances that are relatively rare) he did not believe in long fasts. Then he added: "It is better to adopt a rational and suitable diet and take from one to two and three years to assume the normal." His very language implies that a normal state may be attained earlier by the use of the fast, although he thinks that the slower method is preferable.

With this view I find myself in strong opposition. I am fully aware that a much longer time is required for the evolution of good health if the fast is not employed in preparation for and in initiating a new way of life, but I know of no valid reason why one should be content to take so long when, with the fast, he can safely and advantageously shorten the time required. Must we always await the development of a severe crisis before we avail ourselves of the advantages of a period of abstinence? Must we deny ourselves the benefits that accrue from a period of physiological rest merely because we have no fever and no severe pain? Or can we fast at intervals and prevent the evolution of a body-state that necessitates a crisis? This, to me at least, would seem to be the wiser plan.

To this end the practice, a very ancient one but followed by many people today, of fasting one day out of each week, is rarely adequate. The ancient Aryans abstained from all food and drink one day out of

every seven; the Mongolians fasted every tenth day; the Zends rejected all food every fifth day; the *Bible* mentions the practice among certain of the ancient Jews of fasting one day a week. All of this is certainly beneficial, but our present view is that one day a week of fasting lacks sufficient cumulative value to be adequate to meet the requirements of the chronically ill.

Daniels says, "Missing a meal or two when 'out of sorts' or feeling badly ... is the most common use for fasting. A coated tongue, no appetite and general lack of vigor and energy mean that you should miss a meal or two and give the body an opportunity to right conditions. This simple treatment will frequently avoid attacks of serious illness." Thus, while he agrees that the fast may be employed as a means of preventing the evolution of crises, he too severely limits its use.

I am of the opinion that the rule he gives for determining the length of the fast should apply to the chronic sufferer as well as to the sufferer with acute disease. In discussing how long the fast should be continued, he says: "This is a difficult question to answer in a general way since each case is a law unto itself. One thing is certain, however; to get the best results, no food should be taken until the power of digestion and nutrition has returned. In those having fever, food should not be taken until the fever has permanently subsided. At this time, the appetite will return and the tongue will become clean and moist, indicating that the digestive fluids are present in the stomach and intestines. In general, a fast should be continued in the cases suitable for fasting until the above conditions of the tongue and appetite prevail, until the patient is free from distress, and until he can take, without disturbance, the foods mentioned in the following paragraph."

If the chronic sufferer has a poor appetite or no appetite, if his tongue is coated, his taste foul, if there is a foul odor to his breath and in general he does not feel good, if there is pain and distress, or as they often express it: "Nothing I eat seems to do me any good," why shall he not fast at once and not wait for the evolution of a crisis? If the body gives every indication that it has accepted the proffered opportunity to rest and clean house, what is the need for arbitrarily limiting the duration of the fast?

[Home](#) > [Lesson 46 - When To Employ Fasting; Determining Who Should Fast; How Long And How Often](#) > Article #2: Physical Rest by Dr. Herbert M. Shelton

## **Article #2: Physical Rest by Dr. Herbert M. Shelton**

Commonly we say that the activities of an organism should be proportioned to its nutritive intake and, keeping this in mind, we should have no difficulty in understanding that with the shutting off of income of food, there should be some reduction of physical activity—although how much this reduction should be is not immediately determined.

On the whole, we adopt the position that the faster should rest—physically, sensorially, and mentally. Here we are thinking more of the needs of the sick than of the requirements of the fasting organism. It is the profoundly enervated individual who is in need of rest. The more he can relax and rest, the more rapid will be his recuperation and the more efficient will be the processes of repair that go on in his body. The relatively healthy individual, who is much overweight and who is fasting to reduce weight is certainly not to be placed in the same class with the sick and weak man or woman, who is fasting for physiological rejuvenation.

This, I think, well illustrates a principle that I want to stress at this point: namely that any rule that we can lay down for the conduct of a fast is in the nature of a generality and must be adapted to the individual faster. To insist that all fasters adhere to the same rules to the same extent is to ignore all the various individual factors that render possible or necessary certain modifications of the fasting program that fit it to individual needs and conditions. We cannot deal with people as though they are exact

replicas of each other and as though the condition of one is identical with the condition of another.

The primary purpose of rest is the conservation and recuperation of energy. I make no pretense of knowing what "life-energy" is nor its source. I think that a knowledge of this is not essential to the understanding of our subject. We are all well aware that sleep, which is the most complete form of rest (there being the fullest rest of mind and senses, as well as complete physical relaxation in sleep), is a period of recuperation and replenishment. Rest and relaxation in a quiet place, with no worries or anxieties on the mind, but in the wakeful state, is almost equally a period of recuperation and replenishment. Rest and sleep are nature's grand representative, recuperative and restorative processes; activity and excitement are grand representative processes of expenditure.

Rest does not mean a complete suspension of all of life's activities, as in periods of suspended animation. Indeed, during sleep, certain of the body's most essential activities are most actively carried on. When, in *Life's Great Law*, Dr. Walter stated that the success of the work of the living organism is inversely proportioned to the degree of its activity, he had in mind only certain more obvious forms of activity. The fact is that, the success of the work of the organism is directly proportioned to the degree of its activity in certain basic functions. Witness the processes of growth and repair that are carried on very actively during sleep. Whatever replenishment may mean, in the final analysis, it is a process that is carried on most rapidly during sleep. It may be correct to say that the anabolic activities (that is, the building up processes) of life are most efficient during this period.

I fully agree with Dr. Daniels when he says that "rest from physical exertion is necessary when fasting for any length of time," but only if we limit this to the fasting sick individual. He says that "unless he is really ill the man of average vigor can go without food for twenty-four hours and continue his usual work, but if his condition is such that he should go without food for a longer time, he should rest absolutely." Thus he also makes a distinction between the healthy and the sick individual. I again agree that "if he (the faster) has fever he should go to bed and remain (there) until the temperature is normal and digestion has returned."

When he again stresses the need for rest, saying, "the man who is not possessed of the average physical vigor should not miss more than one meal without discontinuing his usual work and resting," he may overstate the case for rest while fasting. Missing two or three meals without going to bed and resting is not catastrophic in its effects upon the average chronic sufferer. True, it does not provide the benefits that the fast coupled with rest provides.

I do agree that "the idea that man should go without food for long periods of time and keep up his usual work, or indulge in walks across the country, and other athletic stunts, is all wrong." In the early part of this century, when Dr. Daniels was writing, many fasting enthusiasts accomplished stunts requiring extraordinary exertions while fasting. A little later, the marathon runner and man of vigor and endurance, George Hasler Johnson, attempted to walk from Chicago to New York while fasting. These feats of physical strength and endurance are of tremendous value as showing the resources and possibilities of the human organism and they provide us with a basis for confidence when we undergo a fast, but they have no place in any rational plan of caring for the sick man or woman.

Rest while fasting not only provides for comfort but it hastens the processes of recovery. It is important that we keep in mind that the sick man is enervated and that rest is the means of recuperation.

### **Article #3: Pounds That Slip Away by Dr. Herbert M. Shelton**

The big business of losing weight, figure control, diet-in-comfort plans and similar programs have developed into one of the great industries of our age. Everyone considers himself an expert. Fad diets rage for a few months and give away to the next crash wonder. This week it is an ice cream diet. The next it is bananas. The week after that a protein diet, nothing but juicy steaks. Eat yourself *thin*!

Overweight is becoming an increasingly perplexing problem, not only for adult men and women, but for children also. Several facts are responsible for this, but, in general, we may say that the increased abundance of food, together with the increased income of the American people, on the one hand, and the changes in work resulting from the shortening work day, shortened work week, modern transportation, and the many labor-saving devices that take much of the burden off the shoulders of men and women, have resulted in the increase of weight. Just at a time when our reduced labors have reduced our need for food, increased production, artificially increased palatability, and increased income have served to increase our food consumption.

Hygienists are realists. Nothing can circumvent the fact that the quickest, surest, safest way to lose weight is by fasting, and the surest way of maintaining the proper weight level is by refusing to return to the wrong eating habits.

The disappointingly slow method of losing weight by "going on a diet" is rarely very successful for the reason that it is a long drawn-out process requiring more self-control and a much longer period of control than the average person is capable of. A not uncommon outcome of such programs is that, after a brief period, during which time a few pounds are lost, the obese individual returns to his prior overeating and puts back all the weight lost, and often additional pounds. Only rarely does one see an obese individual stick to a reducing diet for a prolonged period.

To begin with, as I have stated in many lectures, and will continue to remind the reader, do not enter upon a fast on your own without the guidance of an expert in the field of conducting fasts. While fasting is perfectly safe as a health and weight-reducing measure, it does involve the complex human organism, and it should be watched over and directed at all times by a qualified person who knows what he may expect, or what trouble signs to watch for during the fast.

How much can one expect to lose? The loss rate of course varies with the individual, but the average for a protracted fast runs around two-and-one-half pounds a day. Is this heavy weight loss safe? It is as long as it is conducted under proper controls and with proper and continuing rest. Let me cite here briefly the most striking advantages of fasting for weight reduction:

1. Safe rapid loss is registered on the fast.
2. The fast is far more pleasant than the reducing diet—the nagging desire to eat is missing.
3. Weight loss may be secured without resulting in flabbiness or sagging of the skin and tissues. However, this is not true of elderly persons.

When the overweight individual undergoes a marked reduction of weight, several indications of improved health follow immediately:

1. Breathing is freer.
2. There is greater ease of movement.
3. There is loss of "that tired feeling."
4. There is a disappearance of the sense of fullness and discomfort in the abdomen.
5. Symptoms of indigestion cease to annoy.
6. Other discomforts cease.
7. Blood pressure is lowered and the load the heart has to carry is lessened.

All of these evidences of benefit are noticeable, but the improvements are commonly out of all proportion to the weight loss, thus indicating that reduction of the amount of food eaten itself resulted in improved health. There is every reason for thinking that the greatly-reduced intake of sugar, starches, and fats and the overall reduction of the amount of food eaten is beneficial.

In 1962, a woman began to fast to reduce weight under my guidance. At the conclusion she told me: "It has been an amazing experience—the pleasure of seeing those pounds melt away. I never saw fat go so fast." Another woman remarked after a fast of fifteen days undertaken for reducing: "I was at a well-advertised health spa. They kept me on a diet of seven hundred calories a day. I was hungry all the time. This fast has been a pleasure."

A third woman said after a week of fasting to lose pounds: "This has been the most remarkable experience of my life. I have enjoyed this fast and rest. I never knew before that people fast, but I have enjoyed it."

Are these expressions typical? Hardly. Fasting is not always the pleasant experience these women found it to be, but it is rarely disagreeable enough to justify discontinuing it until one's goal has been attained. And it is frequently a far more pleasurable experience than many people have in their daily eating habits. In many conditions of life, every meal is followed by discomforts and even actual pain. In these states, the fast is often such a relief that it becomes a joy.

There is always great satisfaction in watching the fat melt away at the rate of two to four pounds a day. To lose nineteen pounds in a week is a highly pleasing experience (there are exceptions in which the weight loss is not so great) for the first several days of the fast. The rate of loss is not uniform and there are periods when the scales register no loss for a day or two at a time. The rapid loss registered at the beginning of the fast does not continue through the whole of a long fast.

Not only is there safety in fasting for weight reduction, there is also greater ease than there is in dieting. One reason for this is that unlike, almost all dieters, the faster is not hungry all the time. His taste buds are not constantly tempting him. The flood of gastric juices is not being constantly activated.

The faster may experience some desire for food during the first or second day of the fast or may not desire food at all. Hunger subsides usually by the end of the third day. And unless the fast is broken for some reason, the faster can continue without experiencing either weakness or hunger.

I state these facts out of my own personal experience but they are also verified by investigations. Two series of experiments carried out by regular medical men in accredited hospitals, have developed empirical evidence sufficient to satisfy the experimenter scientifically that fasting is not only a safe and speedy way of reducing weight, but is also the most comfortable way of reducing.

One of these experiments was carried out by Lyon Bloom, M.D., in the Piedmont Hospital in Atlanta, Georgia, where he conducted a lengthy series of experiments on fasting in reducing weight. This was followed up by Garfield Duncan, M.D. of the University of Pennsylvania who is regarded as an authority on weight reduction and whose independent tests include Bloom's findings and conclusions.

These two medical investigators found that fasting men lose an average of 2.6 pounds a day, while women tasters lose an average of 2.7 pounds a day. Both Bloom and Duncan confirm that the fasters were not hungry. Instead, they reported an amazing absence of hunger with no apparent mental or physical strain. One of the fasters was quoted as saying: "I feel better than ever before in my life." A woman faster, after forty-eight hours without food, volunteered the information that she was not half so hungry as she used to be after missing a single meal.

Bloom is quoted, from the summary of the experiments: "The present preoccupation with eating at regular intervals leads to the misconception that fasting is unpleasant." He stated further, that, in his opinion, as the result of the findings of these tests, fasting is well tolerated by the human system provided there is free access to water. In a later series of experiments, Bloom permitted a faster to go four consecutive weeks without food, with no ill effects. In reading his report of experiments to the

111th Annual Meeting of the American Medical Association, Duncan declared: "although short periods of total fasting may seem barbaric, this method of reduction is marvelously well tolerated." He added that we have evidence that these obese persons fully enjoyed the total fasting periods, due probably in part to their elation that hunger is not a problem while major reductions in weight are being accomplished.

Both men reported that in longer fasts the weight loss levels off to about a pound a day. Bloom stated fasting has also proved to be an extremely effective method of weight control.

In the healthy individual who is fasting only to lose weight, I do not insist on rest in bed but permit considerable exercise—even at times giving a prescribed course of physical workouts. This does not increase the rate of loss as much as one might expect, but it does assist in retaining the tone of the tissues.

The amount of exercise required to reduce weight by exercise alone is far more than the average person is willing to undertake and more than many of them should undergo. To lose one pound of fat requires playing twenty-three holes of golf, sawing wood for ten-and-one-half hours, riding a horse for approximately forty-three miles.

Exercise always has the added hazard of increasing the appetite. During the fast it should be controlled and used only to the extent that the adviser feels desirable for the individual undergoing the fasting process.

While there are varying rates of metabolism, my experience indicates that most obesity is due, not to glandular disorders, but to habitual overeating. There is little truth in the idea that with some people everything they eat turns to fat. The real truth is that they are eating not only more than they should, but more than they really want.

How much weight loss per day is safe in fasting? The answer here is that since fasting is total abstinence, the body itself decides what rate loss is proper. When fat tissue is soft and flabby, weight is usually lost rapidly in the early days of the fast. I have seen losses ranging from four to six pounds a day in fasting. The loss of twenty pounds in a week is not at all difficult in a great many cases.

With those who have a very low rate of metabolism, the rate of loss from the outset of the fast is slow—at times even disappointingly so. Let me reiterate once more, any fasting of more than a few days should be done only under experienced supervision. In all cases where there is any organic defect or chronic ailment, such as heart disease or blood deficiency, even the shortest fast should be supervised. Again let me say there is no essential danger in fasting but one must be properly safeguarded against any danger from hidden conditions that might reveal themselves when no food is taken.

I cite the possibility in order to give the rounded picture of fasting. Let me reassure the reader, however, that such dangers are rare. If the reader is in good health, and follows the proper procedures under proper experienced guidance, the fast should be not only a way of losing poundage, but an exhilarating and exciting adventure, the beginning of a new way of thinking about oneself.

[Home](#) > [Lesson 46 - When To Employ Fasting; Determining Who Should Fast; How Long And How Often](#) > Article #4: Does Fasting Cure Disease? by Dr. Herbert M. Shelton

#### **Article #4: Does Fasting Cure Disease? by Dr. Herbert M. Shelton**

We do not claim that fasting cures disease, but simply that it enables the organism to heal itself. What, then, does fasting do?

1. It gives the vital organs a complete rest.
2. It stops the intake of foods that decompose in the intestines and further poison the body.
3. It empties the digestive tract and disposes of putrefactive bacteria.
4. It gives the organs of elimination an opportunity to catch up with their work and promotes elimination.
5. It reestablishes normal physiological chemistry and normal secretions.
6. It promotes the breaking down and absorption of exudates, effusions, deposits, "diseased" tissues, and abnormal growths.
7. It restores a youthful condition of the cells and tissues and rejuvenates the body.
8. It permits the conservation and recanalization of energy.
9. It increases the powers of digestion and assimilation.
10. It clears and strengthens the mind.
11. It improves function throughout the body.

When we say that fasting is neither a *cure-all* nor a *cure* at all, we do not thereby intend to limit its scope or its field of usefulness. Indeed, the more we learn about this element of nature's hygiene, the more useful we find it to be. As it is used as a rest and is employed where there is great need of a physiological housecleaning, it is effective in all states of disease, even in deficiency diseases, where it is commonly thought that more of certain food factors are essential, the fast has proved to be very helpful. Thus, what may appear on the surface to be an indiscriminate resort to the fast, turns out, upon analysis, to be no more indiscriminate than the employment of water or food or exercise in the same great variety of conditions. When we once grasp the fact that fasting is not employed as a cure and that it is not something that is good in certain so-called specific diseases, but may not be good in other so-called specific diseases, we understand that its use in all the conditions of impaired health is not an indiscriminate use.

- [1. Establishing Your Credentials As An Authority](#)
- [2. The Actual Conduct Of The Fast](#)
- [3. Procedures Incidental To The Successful Fast](#)
- [4. Questions & Answers](#)
- [Article #1: Injury To Fasters By Dr. Herbert M. Shelton](#)

### **1. Establishing Your Credentials As An Authority**

In the light of the great providence of the wisdom of the body as was so beautifully expressed in Lesson Six of this wonderful course of instruction, it is with great humility and concern that I even accepted the challenge of preparing this lesson. I am proud and delighted that the procedures that we have employed in working with people who have been fasting (at the Life Science Health School, Yorktown, Texas) have been sufficiently correct and constructive as to merit the consideration of the school faculty and staff to offer service in whatever way that is necessary.

We have found that the intelligence and wisdom which is an integral component of the body that is undergoing a fast is, indeed, quite able to handle the situation in a most efficient and awesome manner when we refrain from interfering in any way. We can recall one fast, in particular, in which a guest appeared in our presence more dead than alive. Her breath was coming in "thimbles-full" and the exertion of just trying to breathe seemed almost overwhelming. She had to remain in an upright position to be able to breathe at all when it was obvious that she was completely exhausted and should have been reclining in a restful position. We covered her with a blanket and propped her upright in a recliner with pillows.

Through the grace of God or the creative force or power or by whatever name you may call it and the exercise of what proved to be good judgment, the guest improved. Her improvement was slow and frustrating to those of us on the outside of her body that felt something should be done, and we were guided to do just that—we did nothing. We let the innate providence and wisdom of that frail and debilitated body do "its thing" as we sat by and observed, helping as we could from time to time.

In a matter of five days, the first two of which seemed twice their usual length, the "innate intelligence" within that woman's body completely healed her to the point that she was lying down completely flat upon her bed breathing just as deeply as she had ever been able to do in her life without so much as the slightest indication of apnea or difficult breathing.

#### **1.1 Developing "En Rapport" With Your Guests**

To preside over a fast requires many things, all of which are designed to instill faith and confidence within your "guests" that all is going to be uplifting and supportive of life. These guests come into your presence in a fearful state of being, because if they were not fearful for their life, they would not have come to you or the many other practitioners of so-called health before you in the first place.

'One of the greatest things you can do for your guests is to instill a feeling of hope and build a pathway to a faith in themselves to realize that they do, in fact, have within themselves everything that is necessary to bring them safely back to a state of near perfect health and well-being.

Many of your guests will have been in "fasting centers" or "health institutions" of one sort or another before coming to you. You will be "under the gun," so the speak, and your reactions and forthrightness in your responses to their questions, both voiced and implied, will determine how well they respond to your suggestions.

## **1.2 Your Conduct As An Operator of a Composite Personality**

When you have established a condition of "En Rapport" with your guests, you will have formed a composite personality between yourself and your guests. If you have been attentive to their needs and have been responsive to them you will have gained the respect and cooperation of your guests and they will follow your instructions to the very letter. Your guests will thereby gain the greatest amount of good wholesome benefit from their time of fasting under your supervision.

To form this composite personality you will have to get to know your guests in a very personal manner without becoming overly intimate or concerned about their personal affairs, beliefs, and customs. They will share those things with you that they want to share and, as you begin to establish your trustworthiness as a pillar of strength and determination, your guests will begin sharing more and more of themselves with you. This can lead to some rather touchy situations wherein you will be hard pressed to maintain the supervisor-guest relationship to the nth degree, but you must prevail. You are the one who has set yourself up as being the so-called "well" person and the guest is the one who is "sick" or "not with it." You must be part of the solution to their problems as opposed to becoming a part of their problems.

We have found from experience that it is far better to give honest and straightforward answers to the questions you will be asked. If you do not know the answer to your satisfaction, it is far better to simply say you don't know the answer. Tell them you will try to find the answer for them and then make an honest effort to obtain it—one that is satisfactory to both yourself and your guest. None of us knows everything—as Will Rogers is quoted as saying, "We are all ignorant in different things." With the vast amount of knowledge available to the human brain in this day and age, it is no disgrace not to know everything. But you should make a real effort to try to know as much as you can in all subjects relating to Hygiene and Nutrition in their broad sense and application. Bluffing and insincerity are not the hallmark of a dedicated teacher of Hygiene.

## **1.3 Case Histories and Consultation**

Case histories should be as complete and as detailed as necessary to get a good perspective concerning your guests. You need to pry into their affairs as well as you can to determine whether your guest is someone who can benefit from your services. Without their complete cooperation and willingness to turn themselves over to you to get the benefits of your expertise, you are going to be wasting your time as well as that of the guest. When you can find this out early in your program, you will be saving yourself a great deal of trouble and problems. The guest needs to know that fasting is not an easy thing to do, especially one of long duration. He or she should be given some idea of the new and different things that can be experienced, and at the same time, to not be unduly alarmed or frightened at the prospects.

In those cases where there is apprehension or concern, it could be in the best interests of all concerned to feed the guest for a few days while they visit with the other guests who have been fasting to let them learn a little about the effects of the fast. The main point is that you clear the air as much as possible so that the numbers of surprises that the guest experiences through the fast will be minimized.

Upon your acceptance of the guest, you have entered into a contractual agreement more often implied than written but nonetheless a binding contract defensible in a court of law where both parties have their clearly-defined responsibilities.

If for any reason, you feel that your guest doesn't trust you or is uncooperative with you, you will be

well advised to consider not accepting him or her or accepting him or her under certain conditions which should then be clearly spelled out and agreed upon in the form of a written contract. A standard contract format can be made out setting forth the conditions under which you have agreed to work with the guest. This prevents the situation at some later date of "I thought you said I'm a no good so and so." All you have to do then is refer to the contract.

## **1.4 Procedures, Regulations and Rules (General)**

These types of things (contracts, case histories, etc.) can be prepared in advance and kept on file. After you have accepted the guest following your consultation, you can hand him/her copies of the little packet of "dos and don'ts" so that he/she can immediately begin adjusting thinking to the kind of things you want him/her to consider as long as with you and under your supervision and guidance. These contracts need not be lengthy, cumbersome, or difficult of implementation. You should always operate on the KISS (Keep It Simple Stupid) principle, and then you are not later embarrassed by saying something that is obviously unenforceable or redundant.

[Home](#) > [Lesson 47 - How To Preside Over A Fast](#) > 2. The Actual Conduct Of The Fast

## **2. The Actual Conduct Of The Fast**

### **2.1 Pre-Fasting Considerations**

Many times you will find that the guests have had a long history of constipation or perhaps other troubles with the bowels that make regular bowel movements unpleasant and as a result are not indulged until absolutely necessary. When you encounter this sort of a situation, you should consider placing that guest on a pre-fasting dietary of nothing but fresh fruits high in water content for a period of two, three, four, or maybe five days before commencing the fast. Usually this guest will have had at least one and perhaps more bowel movements over this period of time. When some sort of a near normal bowel pattern has been established, then the actual fast can be initiated.

When you are mailing out your follow-up letters after receiving some notice of a guest's intentions of coming to you for a fasting situation, suggest that if he or she is or has been having troubles with his/her bowels or elimination, he or she should eat nothing but fresh ripe raw fruits with a high water content for at least a week before arrival in your center or fasting establishment.

The intent of the pre-fast dietary is to have established a near normal bowel function to minimize the blockage of the bowels when alimentation is resumed at the end of the fast.

### **2.2 Fasting Considerations**

By now you will have established a working relationship with your guest (or have dismissed him or her as someone whom you would rather not work with) and are ready to consider the starting of the fast itself. During the first few days of the fast, you are going to have many opportunities to get to know your guest even better as you continue to work together. You should immediately begin to emphasize the various things that the guest will begin experiencing in the beginning of the fast. Headaches (or other types of withdrawal symptoms) will be quite common with most of your guests, and they should be allayed as soon as possible.

As the guest moves into the fast with each passing day they need to be encouraged to do nothing but rest

without any form of exercise or attempt of any kind to get up a bit and walk around "to keep the strength up," etc. You want him or her to want only to rest. It is when he or she has arrived at this state that the body is able to really begin its' housecleaning operation without hinderence or interference. The real true measure of housecleaning at its very best! When the guest holds on to that idea of reserving energy every day to get up and move around to keep the strength up, that energy is being withheld from the housecleaning procedure. The brain or computer is then in the position of being able to divert all of the efforts to the one job of cleaning out the debris that has been accumulating over the years.

When the housecleaning is finished, the body will again direct the energy back in the muscles and other functions as discussed later in this lesson. It is very important that you have responsible answers ready for your guest's many questions that will be forthcoming at those times when they are experiencing strange and bizarre feelings and symptoms. Your guest can easily become very apprehensive and concerned unless you have good answers and reactions to questions. The actions you take and the reactions you make to the guest's many ploys, whether fancied or real, will have a direct bearing upon his or her cooperation and willingness to follow your directions.

You have to remember that you are the "operator," the "thinker," the "originator" of the thoughts and actions that are being carried out in the "subject," the "doer," the "guest." The guests are very dependent upon you for their guidance and directions so long as the composite personality is maintained. When you lose that relationship, if it is destroyed in any manner, you the "operator" have lost the confidence of your "subject." This can be a devastating experience for the guest, because you have left him or her without guidance at a time when not thinking clearly. This is where self-mastery, control, and poise are necessary. These stem from knowledge, understanding, and a feeling of empathy for your guest and his/her problems. If your dedication to the cause of Hygiene and its wonderful results is not there, you can expect some rough sailing on the seas of public relations with storms aplenty in the forms of unhappy and troublesome encounters with lawyers, courts, and just plain irate former guests. If, on the other hand, you have demonstrated your forthrightness in dealing with the overall situation, you can expect rather smooth sailing with only an occasional storm of any consequence.

As your guest progresses in the fast, certain things must be given due thought and consideration. You very closely observe the guest's progress. If he or she is detoxifying in the usual manner after several days of fasting and resting, all is going well. The actual number of days required to last before the housecleaning is finished will depend pretty much upon the amount of adipose tissue that is available to be used as fuel during the fast. If the guest is well endowed with fuel reserves (obese), many more days will be required to attain the level of a guest less well endowed. In either case, the guest will remain in a state of relative weakness so long as the housecleaning is going on. If the fast must be broken ahead of time, that is before the housecleaning is finished, time must be allowed for the guest to gradually begin eating and making the necessary adjustments to post-fast eating allowing sufficient time for the body to make its necessary adaptations.

Ideally, the guests should be able to arrange their schedules so that they can "fast to completion" or until the housecleaning is finished. On the other hand, there are many things that come into the picture that may mitigate against such an arrangement, in which case, adaptations will have to be resorted to that are in the best interests of the guest.

When the guest is able to "fast to completion," the energies that have been used in the actual processes of housecleaning will no longer be needed for those purposes and will be released. The brain, sensing all of the things that are taking place in the guest's body, will then start shifting energies back into the muscles and the skeletal system of the body. The guest will then begin to feel a new sense of strength and energy returning. The guest will then experience a desire to evacuate the bowels, and the arms and legs will become stronger. At this point in time, it is well to understand and to caution the guest that while he/she may actually feel a surge of strength returning to various parts of the body, it is of very short endurance or for very short lengths of time because there is no reserve to replenish it as it is used up. Many times this strength will be completely used up in a simple little trip to the bathroom or during any type of light exertion. A faster needs to realize his/her actual condition and not overtax him or

herself at that particularly critical time in the fast.

As time progresses, the tongue will begin to clear, the breath and mouth will sweeten, and that nasty taste in the mouth will have changed into one of salivation and the dissolution of the phlegm and mucus of the mouth and respiratory passages. The guest is then ready to be considered for breakfast (breaking of the fast). It need not be broken on that particular day but should be done within the next two to three days when everything has pretty well settled down and the body is really ready for food.

When actually ready for food, the throat and sublingual glands will signal the desire for food, and then it is time to break the fast—at the discretion of the supervisor in consultation with the guest.

### **2.3 Monitoring the Faster**

All during the fast, it is a good idea to keep daily checks on the progress of the fast and its effect upon the guest. Each of you will be interested in various aspects of this procedure, but there are certain things that should be considered by all supervisors in the conduct of the fast. Among those things are notations of the guest's weight, blood pressure, pulse, temperature, urine color, bowel activity, if any, and how the guest is feeling along with your comments and observations of what you are seeing objectively along with the guest's subjective responses to your questions.

As you gain experience in these areas, you will soon find that what are considered to be standards among the usual and accepted standards of the medical establishment are above the standards of healthy people. Blood pressures of 100-110 over 60-55 are not at all uncommon in healthy people. Pulse rates of 50 to 60 are quite normal for guests in mid-life.

Another important item is to be ever alert to the possibility of your guest not taking enough water which can lead to a state of dehydration. He or she needs to be encouraged to drink water every time the urge is there. If that means providing fasters with warmed distilled water to increase its potability, by all means give it to them that way and encourage them to drink water every time they feel thirsty and to not put it off for any reason.

Some signs that your guest is not drinking sufficient water could include: scanty urine or a highly-concentrated nature; a sallow, light, loose skin that does not have the usual elasticity when lightly pinched and released (sort of sticks together); increasing pulse rate; lowering of blood pressure; lethargic or listless countenance and attitude—a detached or "not with it" response; and possible other signs.

If you note any of these things, start questioning your guest and observe closely the amount of water taken from his/her water dispenser. Don't wait for most of the signs to appear to start making your inquiries, perhaps the water is becoming intolerable to your guest and you may need to add a few drops of fresh lemon juice to enhance its taste.

In the course of monitoring your guests, you may have occasion to have questions concerning some of the readings or indications. It may help to get on the telephone and talk with a friend—anyone that you know who has some experience in these matters. Your peace of mind will be greatly enhanced. Reference to the section following "Generalities" regarding the slowing down of a fast can also have meaning for you.

### **2.4 Post-Fast Dietary**

In breaking a fast of longer duration than three days, consideration should be given to the best methods for breaking the fast (see Lesson Forty-eight following) in the best interests of that particular guest. Many things need be considered in making these determinations. Some of these will include the age of the guest, the goals of the guest, the length of time he or she has fasted, the amount of toxic materials that have been eliminated, the stability of the guest from a physical as well as psychological point of view, and the state of rapport that currently exists between you and your guest (sometimes it is best to comply with your guest to salvage as much of a deteriorating relationship as is possible).

Following a fast of 15 days or longer, the post-fast dietary becomes more important with the passage of time in the fast. When a person has fasted that long or "to completion," his or her intestinal flora will have been largely depleted and require a little time to be regained after the realimentation period. An ounce or 28 grams of food may not appeal to the appetite of that particular person who is breaking the fast. This person needs to be encouraged to eat it as gently and easily as possible to reactivate his or her digestive system. Usually by the time he or she has had the second or third ounce (28 grams) of food he or she will begin to have an appetite. By that time, the intestinal bacteria have proliferated and have become active in their own right. The appetite of the guest then picks up gradually, and you can begin giving them slightly larger amounts of food so that by the second day he or she should be able to handle an orange every two hours or perhaps 100 grams (slightly less than four ounces) of grapes or of watermelon. When watermelon is in season and available, I personally think it is one of the finest foods available on which to break a fast.

It seems that from a consensus of opinion that a fast should be broken in the morning so that six meals can be taken—one every two hours between 8 a.m. and 6 p.m. to get the alimentary system working at its optimum capacity. There may be times and circumstances when it will be necessary to break a fast on something other than fresh ripe raw fruits but those occasions should be rare and only where absolutely necessary for some valid reason.

[Home](#) > [Lesson 47 - How To Preside Over A Fast](#) > 3. Procedures Incidental To The Successful Fast

### **3. Procedures Incidental To The Successful Fast**

The conditions alluded to in the preceding materials are idealistic and seldom actually happen in such simplistic forms. Sometimes conditions develop during a fast where the guest will be experiencing unusual amounts of toxic release which may have to be slowed down to some extent. If the fast is causing so much toxic material to be eliminated that the body is unable to eliminate it as fast as it is being released through the usual channels of elimination (i.e., kidneys, respiration, perspiration, and the bowels) and does not resort to any of the vicarious avenues of elimination, the blood will become so toxic that the guest may lose contact with reality (become slightly disturbed or insane). That is because of excessive amounts of toxic materials in the blood that are flowing throughout the body and through the brain in the bloodstream creating an uncontrolled physical situation that is both undesirable and unnecessary. When that condition begins to manifest, it has been found to be a wise precaution to break the fast for a day or two on a fruit that is high in water content such as watermelon, grapes, or oranges and then resume the fast when the situation is back under control. This is one of the main reasons why it is so important that the guest have some appreciation of a few of the things that can happen to them while undergoing a fast.

Actually the above-mentioned toxic condition is that which most people in mental institutions suffer from. None of the people who are responsible for their care and treatment are aware of the cause of their problems, and as a result, nothing constructive is being done for them.

#### **3.1 Be Alert to Guests' Needs—Physical and Mental**

Another consideration of concern when all of the vital signs are within the normal range of variation, is to guard against apprehensions and fears that may be instilled in the minds of your guests by any of your other guests who speak of experiences they've had in various so-called fasting institutions. Many times they will relate their experiences in such a way as to create an illusion of pain, discomfort, or some other danger to the unsuspecting guest. This is another reason why you should pay close attention to your

guests' questions and attitudes so that you can head off those things before they actually become problems (during your informative talks for example).

Also, you will occasionally encounter a guest that seems to have a lot of savvy, has read all of Dr. Shelton's books, and thinks he or she knows exactly what to do and when to break the fast. Usually it is a case where there is little knowledge, and it becomes a dangerous thing. This is especially so in the hands of an inexperienced individual. This is when your orientation talks (information talks) given every day (to those of your guests that feel up to attending them) can be a wonderful tool for de-fuzzing these potentially dangerous situations.

### **3.2 Educational Talks Given to Guests**

Some general observations and suggestions include informative talks on a regular basis so that they become habitual. These talks should be very simple and direct on such subjects as disease; fasting; the 19 components of nutrition; the basic food categories; some discussion of vitamins, minerals, and enzymes; and an exposure to the providence and wisdom of the body. When that has been done, then the cycle should be repeated. Many of the long-term fasters will have an opportunity to hear the talks two or three times. They will not hear them too often, however, because during their fast they are very weak and many of them will not attend the talks until they feel stronger.

Repetition is good, and it takes a lot of it to get even the simplest ideas across. Look at how many times you had to repeat the multiplication tables to get them into your consciousness. The same holds true here. Your talks should be given from a minimum of notes or props so they contain as much spontaneity as possible, and try to avoid the planned or canned type of classroom presentation. Talks should be informal, informative, and as humorous as possible. They should never be longer than 60 minutes and preferably not over 50 minutes because your guests will be in various stages of fasting and eating. They may be readjusting to an eating schedule and will be unable to maintain a very long span of attention to the materials being presented. The fasters who are in attendance have, or at least may have, an even shorter attention span. The talks should be in the simplest language you are able to command, reserving your intellectual prowess for the more argumentative and dissident members of society who seem to look with great respect and awe at the speaker who can keep them spellbound with meaningless, but high-sounding phrases and innuendos.

Your guests will be people from all walks of life with educational backgrounds that vary just as much as they themselves vary as they are progressing through the various stages or phases of the fast and the recovery or rehabilitation program following the fast. Your talks must be geared to that type (variety) of an audience. You will have ample opportunity to express yourself more fluently as you are called upon to give talks before various church groups, fraternal, and social organizations along with various service clubs and others who are looking for an informative speaker—an innovative speaker who has a different story to tell than the one they heard at another meeting they have attended. That is YOU.

We have found that when we teach our guests new information and then tell and retell them this information time and time again, they begin to get the point. You will not, and cannot, make Hygienists of them during your attempts to educate them. The only thing you can ever hope to do is to instill the desire to learn more about the program after they get into it and begin to feel better. The guests will gradually start thinking as their health improves, and they are going to become more interested in the program if you have done a good job of selling them on its basics. It is just like any other program of learning in this sense.

This same rationale and reasoning applies in the case of your guests and the knowledge you may be privileged to impart to them. Most of them are ready to absorb the simpler forms of knowledge you will be able to provide them but will not be ready for the higher aspects of the program until they've had a chance to chew on and digest the basics first. And, for that matter, there is little or no need for them to know more than that unless they are motivated to learn and teach the program to others.

### **3.3 Give Guidance and Direction to Your Guests**

Some other considerations to think about as you are working with your guests include the knowledge that no two fasts are the same. Explain to them that no two guests will have the same reactions and results from a similar fasting situation nor will a guest will have the same reactions and results from a similar fasting situation nor will a guest experience the same kind of a fast the next time he or she fasts. The reasons for this should be obvious, but to review our thinking a little we can suggest that no two objects occupy a single point in time and space so they are starting from different points. Some higher, some lower, some further to the right and some further to the left, etc. And the one individual that has previously fasted is not starting his or her second fast from the same particular point in time or space as the first fast, not even when he or she deliberately tries to do so. Your guests should be advised along these lines of thinking so they can understand what is happening to them when different experiences begin manifesting in this, their most recent fast.

Many of your guests will come to you with a mania or fetish concerning bowel action or the lack thereof. They may be wanting to use laxatives and a series of colonics and all of that kind of garbage. You have to be alert to these things. These guests may even have enema bags in their suitcases to use just in case you will not provide these things for them, and they will use them too until they learn better.

Your guests are looking to you for guidance and direction all during the fast and as long as you are providing that direction and guidance for them, they will follow your suggestions to the best of their ability. You must at every opportunity give them reassurances that there are no dangers involved in the usual fasting situation.

Many of your guests will have lost many pounds of weight and will begin to start worrying about this weight loss. It's necessary to reassure them that they do not need to worry themselves about their weight loss which will normalize shortly after they have returned to eating their regular meals—if they are living Hygienically. Sometimes this takes a bit of doing, especially with any of your guests who lean toward vanity as opposed to the healthy aspects of life. A little reassurance is usually all that is needed. On the other hand, it is important to explain to them that their weight is not going to come back immediately after breaking a long fast. As a matter of fact, it will come back rather slowly at first because their bodies are using just about all of the nutrients that are being provided for energy alone, and it is only when the input of energy in the form of raw materials exceeds the utilization that any weight comes back. So in those who have fasted to completion many times, it takes three to six months to gain their weight back. It is a matter of balance between energy utilization and energy supplied. We have to increase the energy input and increase the exercises just enough to strengthen the body, but not so much to use up all of the reserves that are being introduced into the dietary. If the guest doesn't exercise good judgment in the balance between weight gain and exercise, he will be in for a long siege of thinness.

### **3.4 Breaking Your Guests' Fasts**

The breaking of a fast can be as important as the actual fast itself and must be observed rather critically. In many of your older guests who have had a history of constipation or other bowel irregularities such as hemorrhoids, polyps, or fissures, there will be a tendency for the bowels to be sluggish. If the bowels are not evacuated naturally by the end of the fifth day after the guest has broken the fast, you will need to observe him or her closely. If he or she suggests to you that he/she feels like having a bowel movement but finds it difficult or is having no results, then you should offer reassurance. Explain to them that their systems will normalize if they remain on the Hygienic program and exercise regularly. (I will not attempt to go into detail on the breaking of the fast as the next lesson will cover it precisely.)

### **3.5 How Long Should Your Guests Stay**

Ideally, your guest should plan to stay with you and learn how to eat properly as you continue to look after his or her well-being, as you teach the various ways of combining foods Hygienically. The guest

should plan to stay with you and accept your guidance for at least 2/3 of the time of the fast beyond the fast and the equal of that time would be even better. If the guest fasts for 14 days, they should stay with you at least 10 days and ideally 14 days after breaking the fast.

Another thing that is particularly helpful to those of your guests that can handle the situation is for them to observe various combinations of foods being served to those of the guests who have resumed eating while they themselves are still fasting. For some, this becomes overwhelming and they are not able to do it without great distress whereas with others it presents no problem at all.

### **3.6 General Information Worthy of Consideration**

Your primary concern and intent should be in trying to make your guests comfortable and carefree during the course of their stay with you. There are a lot of little things that come to mind that can be of considerable comfort and solace to many of your guests, especially during some of their more tedious moments during the fast. These can include, but are not limited to the following items. You will think of others from time to time that you will want to share with your guests and other practitioners. There are times when a hot water bottle filled with hot water can be very comforting to the cold feet or the cold back. They can also do wonders in helping to relax the tense solar plexus (see definition). This application of heat to the area relaxes the musculature and allows the nerves to become much less constricted and bound up so that nerve energy is exchanged more freely.

The warming and serving of distilled water in thermos types of dispensers is many times very comforting to the guest. Especially the first drink of water in the morning, and most particularly to that guest who has a habit of drinking something warm upon awakening in the morning. It doesn't have to be hot, simply warmed to about 120 degrees Fahrenheit, slightly warmer than the body.

### **3.7 Helpful Suggestions For Dealing With Your Guests**

In the prolonged fast, distilled water seems to lose its appeal to some of the guests and it can be enhanced greatly by the addition of a few drops of lemon juice as it is warmed as above.

Night lights strategically located around the structure aide considerably in helping the somewhat disoriented guest find their way around at night.

Emergency procedures for obtaining help, especially during the night need to be worked out so as to provide a practical means of making guests wishes known to the staff.

Quiet hours during the day and after a reasonable hour at night can do a lot to add to the comfort of the guests and especially to those who are still fasting.

In your contacts with your guests prior to their arrival after you have made your initial contact with them you should provide them with as much information as you can concerning the types of things to bring along for wearing, recording talks, and listening to music and others that come to mind.

Television and radio should be limited as necessary to prevent their enervating effects upon guests, both themselves and others.

The golden rule applies both to the guests and their interactions between themselves and between the guests and your staff.

Your actual responsibility for your guests will end when they depart from your direct sphere of influence or control but you will want to encourage them to keep in touch with you and keep the communication lines open both ways. You will want to hear about their successes as well as the questions after they begin to live hygienically in their home surroundings. And most importantly you will want to hear about all of their friends and relatives that have been influenced by them after they returned home from their successful fasting experience with you and your effective and efficient staff. Because of this, prior guests may also want to come and spend some time with you to enhance their lifestyles and incidentally

improve their health.

[Home](#) > [Lesson 47 - How To Preside Over A Fast](#) > 4. Questions & Answers

#### **4. Questions & Answers**

##### **What signs and symptoms do you watch for that would indicate that you should breakfast?**

Any of the usual signs of dehydration such as the drying of the skin, profuse sweating, lowering of blood pressure, lethargy, water not being consumed, increase in pulse rate, sudden extreme weakness and/or arrhythmias, confusion, disorientation and/or anxiety neurosis.

##### **How do you handle the family of a guest, all of whom are opposed to the methods and procedures used in conducting a supervised fast?**

It is a matter of education—if you have the time necessary to educate them, they will usually cooperate. If not, you have to place the monkey on their backs and let them know that they will have been responsible for the life and welfare of the person whom they have dissuaded from fasting. After all, fasting is the best way of detoxifying the body that is available to humankind. They will have deprived the person of a chance to do the thing that is needed, often desperately. More often than not the guest has already been exposed to the medical shenanigans which were of no avail and can be pointed out to the family members. Also, you can reassure them that, if for some reason the guest does not respond to the fast, they can always resort to the other methods that they have so much faith in. If the guest is to fast, it is important that he or she be isolated and insulated from the haranguing and enervating pleas of concerned family members.

##### **How would you handle a situation where the guest suffers from angina pectoris and is on nitroglycerine?**

Angina pains are usually the result of exertion in some form or another and rest usually helps to correct the painful situation, without the use of modalities. If the guest can be reassured that all will be well and not become concerned with the various crises of elimination as being detrimental phenomena, all will go well with the guest. Every such situation will have its own particular set of circumstances that will have to be taken into consideration.

##### **How do you determine if the particular disease of a guest is irreversible and how do you explain it to the concerned guest?**

When the situation seems to be quite irreversible, it is best to let the guest know that while it is quite probable that health in general will be enhanced as the result of tasting, there will in all likelihood be no more than slight improvement in the areas of damage or pathology that have been experienced. Any improvement in the body as a whole is going to take the load off of the deranged and impaired part or function and the overall effect is going to be one of improvement.

##### **What about the desirability of having a person on hand who is trained in mouth-to-mouth resuscitation and CPR (Cardio-pulmonary-resuscitation)?**

There are always needs for people with emergency procedures expertise in any situation

whether it be at a fasting institution or anywhere else. It is something that all of the staff of a fasting institution should have some expertise in but is not essential to have one on the staff. The probabilities of requiring those kinds of services in a fasting center are no greater than in any other location and are probably even less under most circumstances. A person who is resting as they should while undergoing a fast is seldom exposed to situation that would cause them to need the services of anyone skilled in those procedures.

[Home](#) > [Lesson 47 - How To Preside Over A Fast](#) > Article #1: Injury To Fasters by Dr. Herbert M. Shelton

### **Article #1: Injury To Fasters by Dr. Herbert M. Shelton**

A man writes me about coming to the Health School. He says he wants to bring his wife with him. Then he adds, "I am not certain whether she would care to be treated as her health is reasonably good, although there are conditions that should be taken care of. However, she was most unfavorably impressed with the methods employed in fasting at *Blank's Institute at Utopia* when I was there six years ago, and I might add that I was well. I cannot recall a single case that seemed to improve by means of fasting and there were patients there at the same time who had been at it for three months and over. Maybe your system is different than *Blank's* was, and I wish you would explain just what you mean by rational fasting."

What is a fast? It is entire abstinence from all food with the taking of one's water and air. It is not a juice diet nor any other restricted diet. Little dribble meals, as Dr. Page so appropriately pointed out, is not fasting. A fast, then, is a fast, no matter where it is undertaken; no matter who conducts it.

But there are innumerable conditions under which a fast may be taken and these determine results. A fast is physiological rest. But physiological rest is not possible under conditions of stimulation, even though one is fasting. In most institutions where fasting is employed, the fast is accompanied by so many enervating treatments that the effects of the fast are nullified.

To require of a fasting patient that he arise in the morning and go to the treatment room for a round of stimulating monkeywork is to enervate the patient and prevent the fast from resulting in an increased elimination of toxins. Massage, adjustments, manipulations of various kinds, electrical treatments, sweat baths, cold baths, sprays, the Blitz Gus, sitz baths, electrical blankets, laxatives, frequent enemas, and a host of other enervating practices prevent the faster from realizing the full benefit of his physiological rest. Only those practitioners who fully understand the role of these methods of treatment are in a position to take rational care of the faster.

The faster should have quiet, rest, and relaxation. Stimulation, excitement, and a lot of activity all produce further enervation and place an added check upon elimination. The faster should be kept warm in order to conserve his energies. Cold baths, cold douches, cold applications, etc., dissipate his energies. The faster who rests also loses less weight in a fast of the same length than the one who is active. This means that the resting faster is in a better physical state at the end of the fast. Also, conserving his food reserves enables him to fast longer if there is need for a longer fast.

The purpose of the fast is not to see how long a man can go without food, nor how thin he can be made, nor how weak he can become without danger to life, but to promote elimination and tissue repair. Every new source of enervation to which he is subjected during the fast helps to retard the attainment of these ends. We should dispense with, either the fast or the treatments, when caring for the sick, as these procedures are incompatible.

Along with the fast, which, as stated, is physiological rest, should go physical, mental and sensory rest. Rest is the opposite of stimulation. All stimulating measures prevent rest. Let no one suppose from this that sedative measures are restful. These are as expensive of nervous energy as the stimulating measures. Treatments of no kind are valuable while fasting, even should we grant their value under other conditions and circumstances.

In the early days of my professional career, I worked a few months in a sanitarium near Chicago that employed fasting in the care of practically every patient that came to the institution. These patients were roused out of bed early in the morning and put through their "course of sprouts." Three mornings a week, I gave each man a massage, followed by a sweat bath and then a cold splash over the whole body, but especially along the spinal column. Three mornings a week, they received electrical treatments followed by alternate hot and cold sitz baths. About eleven o'clock the whole crew of them were lined up on the lawn and put through a series of strenuous exercises. Three afternoons a week I gave them electrical treatments of a different character to those given in the mornings. In addition to this, some of them were given chiropractic adjustments and others were given a thorough stretching on a traction table. All of them were given daily enemas. The rest of the day they spent walking around or sitting and lying around on the sanitarium grounds. They received a daily sunbath.

Many of these patients made remarkable improvement in their conditions despite the great amount of enervating monkey work to which they were subjected, but many of them made no progress at all. With some of those who progressed, their progress was short lived and then they began to slip back.

A few months later I accepted a position with a sanitarium in up-state New York. Here little fasting was employed, but treatment was given in greater abundance. We had a large hydrotherapy department in this place and much more electrotherapeutic machinery than at the first place. We really "gave them the works" in a very scientific manner at this place. The head of this institution was a very up-to-the-minute physician who had practiced medicine for 25 years and who knew about all there was to be known. In fact, he had quite a reputation among the medical men of the state as a specialist in nervous diseases. I never knew just what he was supposed to specialize in, but I became convinced that he specialized in producing nervous diseases.

I had ample opportunity to watch the enervating effects of these forms of treatment when applied to patients who were not fasting. I saw them, after a few days treatment, become so weak they were forced to stay in bed. After a few days of rest they were able to get up and get around again. Then a few more days of treatment and they were back in bed. Not all of them went through such cycles of in-the-bed, out-of-the-bed performances, but those who were not forced to go to bed, showed their enervation nonetheless.

Later I took a position with a sanitarium further up state in New York. Here we had under care an ex-baseball manager. He was partially paralyzed in his left lower limb, so that he could only drag it along in walking and had to walk with a cane. I noticed that as his treatment proceeded his walking became worse. When he would come in for treatment (he was not in the institution, but lived in the city and came in three times a week for treatment), he walked very badly. He would be given electrical treatment and would walk out much better. In spite of this apparent benefit or more correctly, because of this apparent but not real benefit, he gradually grew worse. Then business carried him away for three weeks, during which time he received no treatment. Upon his return, he was walking much better. He resumed treatment and began to grow worse immediately.

I could greatly multiply these kinds of experiences. I could tell you of many such observations. They are the regular feature of the work in all institutions devoted to treating the sick. Every doctor of whatever school sees them daily. He simply closes his eyes to them or interprets them in some manner satisfactory to his mind and continues his enervating treatment of his patients.

Early in my career I learned of the evils of the many and varied forms of treatment that are employed and as I became convinced that a given method of treatment was enervating, I discontinued it. Result: I have eliminated all enervating palliatives from my work. I see not logic or reason in enervating a man

because he is sick. He must first be enervated before he can become sick. How is he to get well if he is further enervated?

I know men who condemn fasting because of certain undesirable results which they say it produces. But I do not see these results coming from fasting. I do see these results coming from the treatment commonly employed while the fast is in progress. I see them also in patients who are fed and not fasted while they are being treated. I am certain that these results come from the enervating effects of the treatment and not from fasting. Fasting, rationally conducted, does not give rise to such results. Anyone may test this for himself by fasting under proper conditions *sans* the treatment.

- [Article #3: Breaking a Fast By Dr. Herbert M. Shelton](#)
- [Article #4: When to Break the Fast](#)

### 1. The Great Day

*I learned that a man emerging from a long fast should not be in a hurry to regain lost strength and should also put a curb on his appetite. More caution and perhaps more restraint are necessary in breaking a fast than in keeping it.*  
—Mahatma Gandhi

When the Great Day arrives, there may be a tendency to feel that the battle has been won, the struggle is over, the problem has been solved. From now on it's "enjoy, enjoy!" Both the fasting supervisor and the faster, with a great sense of relief that the waiting and the denial is at an end, want to get the faster back to the routine and joy of living as soon as possible. And what's the best way to do that? Why we must put some flesh on that scrawny body—we must feed and nourish him back to his normal size and strength. He's been denied long enough. Now we can make it all up to him!

*Whoa!* The end of the fast is only the beginning of the transition to normal living.

#### 1.1 A Critical Period

Adequate, knowledgeable supervision in breaking a fast may be even more critical than the supervision in conducting a fast.

People who have been fasted for serious pathologies have an even more important period to undergo. What has happened during the fasting period is not nearly as important as what will happen when food is restored. And, if serious mistakes are made during this period, the consequences may be unpredictable, up to and including negation of the potential benefits of the fast, or—though extremely rare—losing the life of the patient.

#### 1.2 When to Break the Fast

The decision as to when to break the fast is, of course, of major importance. The condition of the faster

must be assessed from day to day, and a decision made as to the continuation or termination of the fast. This decision should be a mutual one between the faster and the fasting-supervisor.

### **1.3 The Return of Natural Hunger**

If the fast is continued to the return of natural hunger, certain signs will be manifested. The coated tongue usually clears, the mouth tastes fresh and clean, the foul breath disappears. A sense of rejuvenation and well-being are experienced. The desire (or actual craving) for food becomes compelling—and there is a real sense of hunger, which is a mouth-and-throat sensation.

True hunger is not an uncomfortable feeling, but one is conscious of an urgent, but pleasant longing for food. The abdominal sensations, or all-gone feeling, that we usually attribute to hunger, are caused by irritation. Most people have never experienced true hunger. It is possible that one may not experience true hunger at any time during the fast.

Sometimes the tongue does not clear completely, but the indications of the return of natural hunger are visible to the fasting supervisor and the fast must be broken—or starvation will begin.

It is said that the best time to break a fast is when nature gives these signals of the return of true hunger. It is impossible to know in advance just when this will occur. *The fast must never be prolonged beyond this point.*

### **1.4 Premature Termination**

Premature breaking of the fast is also undesirable—breaking it at any time before the return of true hunger is considered premature. Premature termination of a fast may sometimes result in unpleasant consequences. The patient may experience unfavorable reactions when food is offered, and be actually unable to tolerate the food. Or, a succession of unpleasant symptoms may be experienced for a few days. The fast may actually have to be resumed and terminated at a later date.

*Most fasts are broken prematurely.* Although the return of true hunger is considered to be the ideal time to break a fast, and Hereward Carrington maintains that it is actually dangerous to break the fast prematurely, it must be recorded that most fasts are broken prematurely (before the signs of true hunger). I (and others) have observed that usually, if care is exercised in the gradual return to eating, no great harm or serious problems are experienced. Actually, the phenomenon of the return of true hunger is seldom seen.

The majority of fasts are broken "prematurely" for various reasons. Fasts are terminated because of time limitations (the faster must return to work, or to other duties; or he cannot "afford" to stay at the fasting retreat for an indefinite period). Or the body may signal that its vital energy and resources have been depleted to an extent dictating the cessation of the fast (the fasting supervisor must be qualified to recognize these signals). Or the faster may have come to an end of his or her forbearance—mentally or emotionally. These considerations emphasize the importance of professional supervision of the fast.

### **1.5 Length of Fast Not Determined in Advance**

When a fast is undertaken, it is best not to try to determine its length in advance. One should go along from day to day, without setting a definite time limit. It is best to determine to fast as long as necessary, so that the goal may be achieved.

Dr. Alec Burton says, "Some believe that a particular disease, e.g., gastric ulcer, requires a two-week fast, and that the length of the fast is in some way determined by the disease, whether arthritis, asthma or colitis, etc. This is not a consideration. We are concerned only with the requirements and capacities of the individual and not the 'disease' and its treatment. It should be apparent that the only person in a position to make a sound judgement about the length of the fast is the doctor in charge of the case."

Yet it must be acknowledged that there is a certain amount of validity to setting goals when fasting for the remission of certain pathologies, since experience has indicated that such remission usually requires a certain minimum number of fasting days. The professional Hygienist, while not infallible, is qualified to make such predictions, such "educated guesses," so that the faster usually has some idea as to whether a short- or long-term fast may be necessary.

Although there is virtual consensus that fasting to completion has the best potential for producing optimal results, and that premature termination of a fast may make subsequent fasting necessary, some qualifications must be considered. As previously indicated, there are other unmistakable signs that it is time to terminate a fast, for physical, physiological, mental or emotional reasons—and these signs must be heeded.

Dr. Burton says, "Hunger usually only occurs in the very long fast and then only with the almost complete exhaustion of the nutritive reserves. However, it is something that the practitioner should not rely on too much, as it is entirely subjective and there are many questions unanswered about it. Furthermore, because people have never experienced 'true' hunger (i.e., the sensation that is said to accompany the exhaustion of the reserves), they really do not know what they are looking for. Many people say that they do not know whether they are hungry or not. Because hunger is subjective, it should be evaluated in conjunction with the more objective phenomena. For instance, hunger is invariably accompanied by a flow of saliva, whereas a dry mouth is inconsistent with hunger."

## **1.6 Don't Terminate a Fast During a Crisis**

It is not advisable to break a fast while the patient is experiencing a crisis (a period of acute discomfort). It is important to let the crisis run its course before deciding whether it is time to terminate the fast.

A fasting crisis is the manifestation of a symptom, or group of symptoms, during the course of the fast. Such crises may be the manifestation of the release into the bloodstream of the (often morbid) stored by-products of metabolism, producing temporary irritation in various parts of the body. Fasting crises may sometimes be indication of remedial processes and the body's manner of initiating a correction.

Most fasters experience no crises during the fast. Some may experience one or two mild and fleeting incidents, which may run their course in an hour or two. The cleansing processes initiated by the fast are not usually of a violent or disagreeable nature. Most of the excretion of toxic materials is carried on without any discomfort or inconvenience. Extremely toxic individuals may expect to experience some discomfort—which is an indication that they were greatly in need of a fast.

Various crises have been noted in observing thousands of fasts—headaches, nausea, vomiting, skin eruptions, and others.

Headaches may appear early in the fast, and, except in some unusual cases, disappear in a day or two. Nausea and vomiting (or, sometimes, nausea without vomiting) occur in about 10% of patients, sometimes in the early stages only, sometimes continuing for longer periods. If vomiting persists, dehydration may be a threat (especially if the faster cannot retain water), and it may be necessary to terminate the fast. In some cases (extremely rare), diarrhea accompanies vomiting, resulting in great fluid loss, and the fast must be terminated.

If pain is being experienced, the fast should not be broken until the pain subsides (as it usually does, in short order). It is best not to break the fast until the day after such pain is experienced. As a general rule, wait until well-being and comfort return before breaking the fast.

Sometimes (though this is infrequent), a mild malaise (a borderline nausea) will continue throughout the fast, and will not disappear until the person resumes eating. Obviously, this type of continuous mild malaise would not be a contraindication to terminating the fast, if such termination appears to be advisable.

Some people need very little sleep during the fast, but a return to eating soon results in a need for more

sleep. Some people do sleep a great deal, especially during the first week or so of a prolonged fast. The body does not deprive itself of needed sleep.

Some toxic individuals experience a rise in temperature during the fast. Usually the temperature, pulse rate, and blood pressure are lower soon after beginning the fast. The heart rests, and there is a slowing of circulation. After the first week or so, weakness and dizziness are often experienced, concurrent with the inevitable loss of weight.

Dr. Burton says that the weakness experienced by the faster is "essentially a locomoter weakness—a weakness in the muscular system and the organs of locomotion. It is not a weakness in the vital organs." The energy of the organism is being diverted and utilized for detoxification and healing. Under these conditions, the muscles don't need the energy—they can wait for the time being.

Dr. Herbert M. Shelton says, "It seems that often (during the fast) there is a pooling of blood in the abdomen. There is less blood in the brain, although thinking is clear. Under these circumstances, to arise quickly from the horizontal position to the vertical, may result in dizziness and even fainting because the adjustment of the circulation in the head is not as rapid as the speed with which the change of position is made. To avoid possible fainting, which may occur in occasional cases (although it is of no consequence), one should arise slowly. Instead of forcing your organism, come slowly to a sitting position, sit on the side of the bed for a brief time, and then slowly rise to a standing position."

After eating is resumed, the weakness and dizziness gradually disappear—say, in about a week or so, concurrent with weight gain. The precautions about gradual change of position, and continuation of bed rest, should continue until these conditions improve.

## **1.7 Why Caution Is Necessary in Terminating Prolonged Fasts**

There is a broad range of opinion as to the best method of breaking a prolonged fast—but all the experts agree that the reintroduction of food to the fasting organism must be gradual.

It must be understood that the fasting period, and the subsequent return to eating, has necessarily subjected the organism to two extremely stressful situations, within a relatively brief period of time.

When food supplies are stopped, the body does its best to adjust to the new conditions. The digestive organs are no longer required to perform their usual functions, and virtually cease to exercise them. No signals are forthcoming for the secretion of gastric enzymes and juices, or for the normal secretions in the intestines.

Without food to keep it expanded, the stomach contracts; the intestines and colon do the same. Bowel movements usually cease altogether after the first few days of the fast; although, sometimes, when debris is trapped in diverticula in the colon, it is gradually expelled, as it is "squeezed out" as the walls of the colon contract; in this case, small bowel movements may continue for a week or longer. In some colitis patients, who have been experiencing acute diarrhea, the diarrhea (at a reduced rate) may continue for a time during the fast.

In any event, the organs of digestion are almost completely at rest, while other organs and processes take over and work overtime. The organs of elimination initiate a heroic cleansing operation, through the urine, the lungs, (the mucous membranes and the skin (and sometimes, as has been indicated, through continuing bowel movements).

The organism mobilizes its reserves, so that the functioning organs and tissues continue to receive nutriment. Surpluses of stored materials in the body are utilized for this purpose. The vital tissues are nourished first from the food reserves in the digestive tract (where there is usually a three-day supply), and then the fat, deposits, and abnormal growths are broken down, so that the nutrients may be salvaged and absorbed, and wastes eliminated—by the process of autolysis—the disintegration of tissues by the body's own enzymes. This is a normal part of physiology, but is speeded up and enhanced by fasting. The wisdom of the body is its own safeguard, and it uses first and least important stored materials; the

essential organs and tissues of the body, such as the heart, nervous system, lungs, and other vital parts remain intact, and no cells are lost.

All of the resources of the organism are mobilized for this metamorphosis, and the body strives to utilize and maintain its available energy to perform the cleansing, nourishing, and healing functions initiated by the withholding of new food supplies. The organism proceeds in an orderly manner, always in the same direction, every part of the body cooperating for the preservation of life and for cleansing, nourishing, and healing.

When the fast is broken—particularly when it is broken before the return of true hunger—the body is subjected to an even more stressful situation than that which occurred when the organism was forced to adapt to the cessation of feeding.

The body has temporarily lost its ability to digest food in the usual manner. When foods are again offered to the organism, it must be given an opportunity to gradually regain its power of normal function. The longer the fast, the more care that is required in the method of its termination.

Methods of breaking the fast are designed to restore intestinal function and reactivate digestive faculties which have been resting. The body must make changes and adjustments in physiology, to accommodate to the new situation.

If the first food is of such a nature that the organs are not able to handle it, the patient may become nauseated and vomit the food. This violent reaction can cause mental and physical harm; and the fast must be resumed, at least for a day or so longer, perhaps even more.

As a rule, however, the first food is welcomed and tastes delicious. If it is freshly-squeezed orange juice, or fresh fruit, it usually tastes like nectar or ambrosia, and the faster looks forward to the next meal with anticipation and delight.

If the wrong kinds of food are offered, perhaps the patient may enjoy the food, but there may be little or no digestive response, and the food may decay or ferment. If peristaltic action to move the food along the digestive tract is absent, impaction may occur, with the possibility of uncomfortable constipation.

As previously indicated, opinions differ as to the one best method to break a fast, and it is probable that there is no one best method. After a prolonged fast, only an experienced fasting supervisor is qualified to offer the first foods and to observe the reactions of the patient, and to modify the method, whenever indicated. This must be emphasized: the care that is necessary in breaking a fast is in proportion to the length of the fast and the condition of the faster.

Dr. Shelton says, "Almost every advocate of fasting has evolved his own techniques for breaking a fast. There seems to be a tendency for each man to assume that his own techniques are best. There may be several techniques, each one of which is as good as the other. The chief requirement in breaking a fast is to use simple, wholesome food and feed this in keeping with the limited digestive capacity of the faster. Time is required for the digestive secretions to begin to be produced in normal amounts and, until they are secreted in normal quantities, the ability to digest food is limited."

## **1.8 Examples of Methods of Terminating Prolonged Fasts**

Some of the foods and methods that have been used in breaking prolonged fasts include:

Dr. Allan Cott, in *Fasting As a Way of Life*, page 27, advocates mixing a pint of boiling water with a pint of grape, orange, or apricot juice, and having the patient sip two or three teaspoons of this mixture every ten to fifteen minutes throughout the day, finishing the full quart by bedtime. The second day he gives up to a quart of undiluted juice, four ounces every two hours. The third day he gives whole fruit; the fourth day salad and some cooked food.

Dr. Otto H. F. Buchinger breaks the fast with apples, later (the next day) followed by salads and cooked food.

Paul Bragg breaks the fast with cooked tomatoes, later (the next day) followed by salad and cooked food.

Some fasting supervisors advocate breaking fasts with vegetable broths, especially for people who have been fasting for severe digestive problems (such as ulcerative colitis), followed in due course by small amounts (if tolerated) of salads and fruits.

Other foods are also advocated and used for breaking fasts, but they are so far removed from Hygienic concepts that I will only refer to them very briefly (flesh foods, milk).

Years ago, I heard a lecture by Dr. Theron Randolph, a renowned Chicago allergist, who fasted his patients for five days, and then experimented with offering various foods to determine the offending foods causing the "allergic" problems. He said that he usually broke these fasts with lobster! His rationale was that people usually become allergic to foods which they eat habitually, and this is not apt to be the case with lobster. He used lobster to break fasts in order to guard against allergic reactions from the first food offered. This is, of course, a far cry from Hygienic methods and principles.

Breaking fasts with sandwiches, popcorn, lobster, and a variety of difficult-to-digest foods may or may not cause overt negative reactions, but they will certainly add to the stress of an organism which can ill afford it. None of the above methods are utilized by Hygienic fasting supervisors, with the exception of the vegetable broth method, which is sometimes utilized by Hygienic professionals in certain unusual cases.

## **1.9 Hygienic Methods of Terminating Prolonged Fasts**

For many years, Hygienic fasting supervisors have been breaking fasts with fresh, uncooked fruit juices or vegetable juices. Fruit juices have been most commonly used. Orange juice is generally preferred.

Some use four ounces of unstrained, undiluted juice for the first feeding—some strain and dilute (with distilled water) the first juice, strain (but not dilute) the second feeding, and give the unstrained, undiluted whole juice for the third feeding. Some give four ounces every hour, or eight ounces every two hours for the balance of the first day (the first two feedings having been four ounces each, one hour apart). If, as sometimes happens, the person becomes satiated after five servings, the frequency is curtailed. Some give eight ounces every three hours after the first two feedings, and a whole orange for feedings every three hours for the next day or two.

Dr. Vetrano has changed from juices to whole fruit for breaking most prolonged fasts. She serves one-half orange every two hours the first day; the second day a whole orange every two hours. Or she varies the second day by serving one piece of a different fruit every two hours—six servings. She sometimes breaks fasts with tomatoes for those who desire not to gain weight. For people with a history of digestive problems, she may still break the fast with juices.

Dr. Vetrano believes that good bowel action is established sooner when breaking fasts with solids rather than juices, and that most people prefer the opportunity for chewing.

Whether the first food is liquid or solid, it should be "chewed" or well insalivated. During the post-fasting period, proper mastication is extremely important to avoid overtaxing the digestive system at a time when it is under stress to regain its full-functioning capacity.

Dr. Shelton says he sometimes uses a warm vegetable broth to break a fast, in those rare instances when the faster has difficulty with raw juices.

Whenever the individual feels unable to take the amount offered, amounts may be reduced, or the feeding skipped.

Dr. Shelton says that on the third day the faster may be given an orange for breakfast, two oranges at noon, and three oranges for the evening meal. The fourth day a variety of foods may be given, such as melon or grapes or other fruit for breakfast, other fruit for the noon meal, and a vegetable salad for the

evening meal, with a cooked nonstarchy vegetable, if desired. Dr. Shelton says that, beginning with the fifth day, a protein should be taken daily with the vegetable meal. He says that, after a few days, a cooked starch may be taken with the vegetable meal on some days, instead of the protein, if desired. (See subsequent discussion in this lesson relative to the inadvisability of offering cooked food so soon, unless absolutely necessary.)

My own experience and preference is for four ounces of strained, diluted orange juice for the first food. If well tolerated, four ounces of strained, undiluted juice is given an hour later; and eight ounces of whole (unstrained, undiluted) orange juice two hours later. Two or three hours later, one or two whole oranges are served, and again in three hours.

The second day—whole fruit at three-hour intervals; the third day—two or three small fruit meals, and a small salad in the evening, if desired by the faster—otherwise, continue the fruit. I do well on this regimen, so does my husband.

I like to start with diluted and strained juice to reduce the possible hazard of the insufficient mastication of the tough connecting citrus membranes; also, to reduce the acidity of the first juice.

I like to break a fast in the morning, but there is no compelling reason why a fast may not be broken at another time during the day, especially upon the return of true hunger. I like the morning best because of the opportunity to offer several "meals" before bedtime.

Some fasting supervisors recommend more stringent regimens, and some more generous ones. Arnold De Vries recommends five days of juice after a thirty-day fast, but qualifies this as a general guide.

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > 2. Easing Into A Varied Diet

## **2. Easing Into A Varied Diet**

Some people can be eased into a varied diet sooner than others—the fasting supervisor makes this decision, based on how the individual reacts. Most people are able to take only very small quantities of food for several days, and they should be given no more than they can comfortably handle. They are usually satisfied with small quantities of food at the outset, and, in truth, only small quantities are required.

The reason the faster is unable to take larger amounts is because the stomach has contracted during the fast. Some fasting supervisors serve four small meals daily for a week or more, to enable the individual to regain weight and strength somewhat faster: breakfast, lunch, dinner, and a small evening fruit snack.

Dr. Shelton says that by the end of the first week, the faster should be able to take normal amounts of food.

### **2.1 Overeating After the Fast**

Some people soon demand large quantities of food to compensate for previous restrictions. Those who have a tendency to overeat after the first few days of eating should, of course, be restrained. Constant overeating will again distend the stomach, after which the person does not feel satisfied unless he eats to fill the distended stomach. Those who are allowed to eat too much may find that the overeating may delay the restoration of the body's normal ability to digest the food comfortably.

Most people have no digestive problems after a fast (if the fast is broken prudently)—some do have them, even if they have not been conscious of digestive problems in the past. Dr. Vetrano says that most people come for a fast with a slight inflammation of the digestive tract, whether or not they know it.

Such people are well on the road to making themselves sick all over again, if they are allowed to overeat in the initial period following the termination of the fast.

Charles W. Johnson, Jr. (*Fasting, Longevity and Immortality*) says that if a "monster of appetite" is turned loose after the fast, it becomes very difficult to control, resulting in a loss of much of the fasting benefit, as well as the probability of significant harm. Listening to the appestat at this time may misguide you.

Those who are very thin and slow to gain weight should ignore their weight. Gaining strength and restoring efficiency of body function is much more important. They should not overeat and try to eat fattening foods. They should be satisfied and accept the gradual weight gain that will surely come at the proper time. Even if one is gaining only a pound a week, that is twenty-six pounds in six months. In any event, the weight will stabilize in time.

Dr. Shelton says, "After a fast of considerable length, there is a period of several days, lasting up to two weeks, during which the individual feels hungry most of the time. If not carefully guided, he is almost sure to overeat. If he will control his eating until this initial period of hunger has passed, he will settle down to a more normal appetite and the danger of overeating will pass.

"Uncontrolled, he may eat so much during this period that he loses much that he gained in the fast. One important advantage of fasting in an institution is that control continues until the normal eating level is stabilized. In such an institution the patient's diet is carefully supervised; he is not permitted to overeat. At home, he must be a more self-disciplined man than the average if he is to avoid overeating."

Dr. Shelton also says, "The animal breaks his fast on whatever food is available at the time he resumes eating. On the whole, animals seem to be better controlled than man. They are not inclined to glut themselves when they break a fast, but may take but a small portion of food in doing so. A dog that has fasted for nearly a month, for example, may take but a few sips of milk at a time and may refuse all flesh for the first four to six days, after he resumes eating. If man's intuition was still as reliable a guide to eating as is that of the animal, I doubt that we would need to supervise the breaking of a fast." If possible, one should try to stay at the fasting retreat long enough to gain enough weight to look "presentable", to family and friends, if one is very thin. If not possible, it is best not to worry about it. The family and friends will gradually observe the new bloom of health as the months go by.

Many people who had been chronically underweight before, the fast experience such an improvement in assimilation after the fast that they achieve a more normal weight by the time the weight stabilizes. This is due to the increased ability of the cells to take up and appropriate nutrients, which always results from fasting. *Weight gain is often less effective after sickness*, because of damages from toxins and drugs.

Upton Sinclair, in *The Fasting Cure*, maintains that after a fast we "bounce" back to our "ideal" weight, sometimes less and sometimes more than the prefasting weight. Upton Sinclair changed himself, after several fasts, from a very thin "ectomorph" to an athletic "mesomorph."

On the other hand, people whose target is weight loss may be significantly benefited by fasting. Dr. Edgar S. Gordon of the University of Wisconsin Medical School, says that people who gain weight easily probably have a low metabolic rate. They convert glucose to fat much too rapidly and don't produce enough available energy. Dr. Gordon's experiments with animals suggest that a fast may "break the metabolic block," producing subtle endocrine changes that make food assimilation more efficient. A report in *Lancet*, a British medical journal, supports the view that hormonal changes brought about by fasting may continue to promote weight loss even after eating is resumed.

This does not consistently happen in all cases of obesity, but it is an important potential benefit of fasting for weight loss. Of course, nothing in the world will keep weight off if the individual resumes gluttonous eating habits.

Fasting does lead to a new awareness of the difference between hunger and appetite, and reeducates the taste buds. If the faster can be helped over the initial critical period, he can achieve an alteration in his

eating habits. Many people come off the fast with a passion for fresh fruits and vegetables. A 1976 *British Medical Journal* report says almost all fasting patients "admit to a radical change in previous eating habits."

Although a fast does, for the most part, put appetite into alignment with the body's *real* needs, Dr. Allan Cott says (*Fasting As a Way of Life*, p. 25), "The wise person eases into a sensible refeeding program. Easy does it if you want to continue feeling wonderful. ... In effect, the body is reeducated by a fast. It 'unlearns' habits of overeating and 'polluting.' It is 'born again.' It inclines toward a natural state. It wants only as much food as is required for maintenance. It prefers the kinds of food that are natural to the taste and harmonious to the digestive system." He cautions that you should adhere to a careful refeeding schedule for the same number of days you fasted. If you do this, "the likelihood is that, when you return to a regular eating pattern, you will be eating more selectively and austere, which is all to the good."

After about two weeks, or perhaps a little longer, the feeling of being hungry all the time tends to disappear, if the "monster of appetite" has been kept under control.

## **2.2 Permanent Control of the Eating Program**

Dr. Cott says that after fasting, there is a much better chance for permanent control of the eating program than after any diet. He says, "The system now wants to reject food in excess of the needs of the body. You should now be able to gain a new perspective on food and a new relationship to food that can keep you from overeating or from eating undesirable foods. Fasting and a sensible refeeding program have led to this desideratum."

Dr. Cott also says, "After a long fast the palate is restored to pristine purity. It prefers the taste of foods that are simple and whole and natural. It tends to reject processed and fragmented foods, as well as alcohol and tobacco."

Dr. Shelton says that if fasting is being used for the alleviation of a chronic disease—even if the patient has undergone only a short fast (less than fourteen days)—it is usually desirable to utilize an eliminating diet for a period of time after the termination of the fast, perhaps for as long as a few weeks. An eliminating diet is a diet low in proteins, carbohydrates, and fats, which causes the cells to use stored reserves to meet their requirements. During such a diet, the body can eliminate toxic matters and accumulated wastes, but never as well as during a fast. Obviously, an eliminating diet would not be recommended if the person had previously fasted to completion.

## **2.3 Eat All-Raw Food As Long As Possible**

When the individual progresses to a varied diet, a variety of *uncooked* foods may be eaten. Even if the person intends to return to the use of some cooked food, this should be postponed as long as possible.

Careful management of the food program should continue for at least two to three weeks after breaking the fast. The fragile situation in the body is only gradually eliminated, as the digestive system slowly returns to its normal efficiency.

Some extremely debilitated or anxious individuals are impatient with their slow and gradual regaining of strength and weight, and find it extremely difficult to stay on all-raw food. In such cases, it might be advisable to allow small amounts of cooked food, at the evening meal only.

But it is really much better to eat moderately of good, whole, raw food, and efforts should be made to allay the misgivings of the post-fasting individual. Adaptations are being made, and will be accelerated by the higher quality of the whole raw food.

During this period, it is extremely beneficial to stay on the all-raw-food diet, if at all possible. The longer the all-raw-food diet is maintained, the better start the person will have. One should refrain from polluting the relatively clean bloodstream with the pathogenic debris of cooked food indefinitely, if

possible.

After the fast, the body needs whole, raw food, and will not welcome cooked food, in which all of the enzymes have been destroyed, along with many of the vitamins and minerals. In addition, the amino acids and fats have been changed and made less digestible and sometimes toxic, and the balance of nature has been altered.

An optimal diet of whole, unprocessed foods is especially important for the first, few weeks (or even months) after the fast, when the body is regaining normal weight, and new protoplasm is being built.

The body chemistry is basically determined by the foods that are eaten, though other factors, (exercise, sunshine, fresh air, etc.) have some influence. While the causes of disease include chemical, bacterial, mechanical, and mental factors, chemistry dominates the efficiency of the physiological functions of the organism, other factors being secondary to the chemical condition of the body.

The complex chemical balance of all food nutrients is altered by heating, and it has consistently been demonstrated that superior tissue, and superior health, result from a diet of uncooked food.

Remember that the nutrients available in raw food exceed those in cooked food by several hundred percent, and after a prolonged fast, this is a critical time to decide— with what quality of tissue will you replace the tissue you have discarded?

The faster and the fasting supervisor should make this decision cooperatively, always with the thought in mind that the faster has already made a tremendous investment, which can be either safeguarded or threatened by the post-fasting food program.

## 2.4 Protein Needs After the Fast

After a prolonged fast, a slightly greater amount of protein than usual may be necessary, *if not in excess of the digestive capabilities of the body*. Immediately after a prolonged fast, the body cannot handle a large quantity of protein foods.

Concentrated proteins are more difficult to digest than other foods, because they are the most complex of all the food elements, and their breakdown and utilization are most complicated. The body can utilize only a limited amount of protein in the immediate post-fasting period.

Dr. Shelton says, "Nothing is to be gained by overfeeding following a fast. The hurry to gain weight and strength causes many to demand excess quantities of protein, thinking that protein is utilized in direct proportion to the amount eaten. In *The Nutrition of Man* (1907) Professor Russell H. Chittenden of Yale University, detailing his experiments covering the establishment and maintenance of nitrogen balance at many levels of nitrogen intake tells us: 'The fasting man having lost largely of his store of protein can replace the latter only slowly, even though he eats abundantly of protein food. ... The human body does not readily store up protein and this is true no matter how greatly the tissues are in need of replenishment. Overfeeding with protein does not lead to corresponding results, owing primarily to the peculiar physiological properties of protein; its general stimulating effect on metabolism, the tendency of the body to establish nitrogenous equilibrium at different levels, and the fact emphasized by van Noorden that flesh deposition is primarily a function of the specific energy of developing cells. ... It is generally considered as a settled fact, that in man it is impossible to accomplish any large permanent storing or deposition of flesh by overfeeding. Similarly, it is understood that the muscular strength of man cannot be greatly increased by an excessive intake of food. ... We may call attention to the well-known fact that in feeding animals for food, while fat may be laid on in large amounts, flesh cannot be so increased by overfeeding.'

Shelton continues, "It is obvious that there is nothing to be gained by the excessive intake of protein, following a fast. The body can make use of only so much protein in the post-fasting period, and must excrete all unused protein. ... Nitrogen retention is increased both by mineral and by carbohydrate intake and it is more important that the diet contain adequate quantities of these than that it contain an excess of

protein."

## 2.5 An Interesting Phenomenon

An interesting and probably significant observation made by Charles W. Johnson, Jr. in *Fasting, Longevity and Immortality*, page 26, pertains to a fact (which I have often observed) that, subsequent to a fast, more weight may be gained than can be accounted for or justified by the amount of food that had been eaten. It is usually maintained that it takes three thousand accumulated calories to gain or lose a pound, and I have observed that this is far from a consistent result, either when fasting or eating.

Johnson says, "My notes show that I broke my forty-day fast on March 28, 1964, but four days before, on the thirty-sixth day of fasting, I put in a hard day's work getting the garden ready for planting. From March 22 to 28 my weight stayed at 135-136 pounds. This brings up what may be the most important mystery of fasting.

"We can calculate the energy that is needed to keep our heart, breathing mechanism, and brain functioning. Adding in a little for minimal physical activity, we can conclude that a moderately inactive faster should lose almost a pound of weight per day. That is, in the absence of food to burn for energy, the body must burn, or catabolize, almost a pound per day of its own weight to 'keep going.' During most of a fast this is a typical weight loss figure.

"Nevertheless, here I was, near the end of a forty-day fast, feeling more energetic than earlier in the fast, doing more physical work, and losing *no* weight! Impossible, of course, and I foolishly ignored the fact—the absence of weight loss—assuming it to be the result of faulty measurement or observation. (How often we scientists miss something important of this sort simply because we *know* it is impossible and therefore *refuse* to notice it.) Subsequently, however, I read that others had noted the same phenomenon, and in some cases with great concentration.

"There appears to be a clear-cut violation of a sacred law of physics here—the law of mass-energy conservation. Some mysterious source of energy is supplying its energy for our body's use."

Johnson says that after his forty-day fast, he realized that he was not eating and drinking enough to justify his weight gain. "The violation of mass-energy conservation, manifest in the last days of the fast by lack of weight loss, was continuing now that I was eating. It was now taking the form of greater weight gain than my food and water intake could justify ... *surely important research remains to be done here.*"

Dr. Cott says, "Once you resume eating, some weight gain *naturally* occurs. The body retains fluid, which translates into weight because of the sodium content in food. For a time after any fast, this will be more weight than is metabolically balanced for the amount of calories being consumed."

This may be a partial explanation for the phenomenon observed by Johnson (and others), but does not by any means completely account for the inconsistencies in weight loss and weight gain and their relationship, to the calories consumed.

## 2.6 Beware of Cooked Food and Other Compromises

For those who do eventually return to a varied diet which includes cooked food—be on your guard! Compromise may follow compromise and you may find yourself back on the same destructive path that led to your problem which necessitated the prolonged fast.

A return to your old habits may negate all you have done and start you back on the downward path. This is the time to reinforce your decision to persevere in Hygienic living, and experience even greater health improvement in the years to come.

It may be as much as a year before you consolidate your gains and evolve into the health and strength you envisioned when you undertook your fast. But it will surely come to pass if you continue to study

Natural Hygiene and *live* in accord with your natural requirements.

Those who do use some cooked food must be ever wary of going too far. Once you cross over from nature's most perfect foods (raw and unchanged), it is all too easy to make this exception and that—desserts, processed foods, etc.

If you will be eating *some* cooked foods, wait as long as possible after the fast to start, and then:

1. Reserve at least some days for all-raw food.
2. Never eat cooked food more than once in a day, as part of a meal starting with a large raw salad.
3. Be certain that your overall diet includes no more than 20% of food that is not whole and raw—preferably no more than 10%.
4. Be very strict with yourself—at least during the first year after a prolonged fast. If some of your symptoms return, be sure to immediately "back up" and keep as close to an all-raw-food diet as you can possibly manage.

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > 3. Symptoms After The Fast

### 3. Symptoms After The Fast

Sometimes fleeting symptoms will occur or recur for a short period after breaking a prolonged fast. Some people experience mild sore throats, canker sores in the mouth, edema (usually slightly swollen ankles). Sometimes there is a mild recurrence of the original problem—or a very temporary painful episode.

These usually are manifestations of the organism's efforts to affect necessary adjustments during the period of transition from the fasting state to the necessity for processing renewed food supplies.

No palliation of such symptoms should be attempted, and *it is not necessary (nor advisable) to start fasting again at this time*. Get a lot of rest, and continue eating carefully, *preferably all-raw food*, and these symptoms will gradually recede.

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > 4. Transition To Rational Living

### 4. Transition To Rational Living

Usually the transitional period is not really difficult—most of the time there are no real problems.

The first bowel movements may be normal and easy—they are usually very dark and malodorous, gradually changing to a normal color and losing the foul odor. If you experience some difficulty, don't strain or worry—tell your fasting supervisor, who will help you.

After you resume eating, your bowel movements will probably be quite soft, but will gradually progress to the normal consistency.

After a few meals, the faster begins to feel better, and may experience a sense of euphoria. S/he is so happy to have successfully culminated the fast—so happy to be enjoying the pleasures of food again. There may be delusions of returned strength and well-being, and the desire to do something foolish, like indulging in strenuous activity. But, actually, the dizziness and weakness retreat only gradually. One

must come back slowly. The body will appreciate being allowed time to gradually adapt to the new situation.

Johnson says that the miraculous power of the fast produces "unquenchable exuberance" and enthusiasm for life, especially for a period immediately after breaking the fast. He says, "The gourmet does not know the true feeling of tantalized taste buds until he has broken a fast of at least several days on any simple food." All fasters and all fasting supervisors will agree with Johnson's eloquent expressions of the euphoria experienced after the fast.

If one has not fasted to completion, the tongue will gradually clear—it usually takes several days (sometimes longer) to eliminate the coated tongue and bad taste.

Dr. Shelton says, "Bed rest should be continued through the first week of eating and activity begun very gradually. It is common for the faster to want to become active as soon as he resumes eating. This is unwise. He is not so strong and he does not have the endurance he thinks he has. Some fasters want to take long walks as soon as eating is resumed. Such activity is often indulged in to the extent that it retards recuperation and causes the individual's weight to stand still. One must take it easy for a few days before becoming normally active."

As vigor gradually returns, one should begin—cautiously at first—taking short walks, and some easy exercises. It is very important to gradually build up the capabilities for vigorous exercise, in accordance with the condition of the body, as this will assist restoration of the normal digestive ability.

The ability to process and assimilate food will be greatly enhanced following a fast and its proper termination, and after an initial period of adjustment. Resting after each meal will also greatly enhance digestion, weight gain, and renewed vigor.

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > 5. Drugs And Other Poisons

## **5. Drugs And Other Poisons**

*Very important!* It must be remembered that drugs and other poisons are a greater threat after the body has been cleansed by a fast, because the "calluses" are gone. The tolerance level has been lowered—the body no longer tolerates toxins and will react strongly for their elimination.

When the individual was tolerating toxins, he (or she) was developing disease and gradually killing himself. A lower tolerance level is a tremendous step forward, but it leaves one more vulnerable. So it is important to stay out of hospitals and stay away from drugs and all other toxic materials. Avoid smokers, carbon monoxide fumes, and polluted air to the greatest extent possible.

It is, of course, not necessary or advisable to use food supplements after the fast, nor at any time. After the fast, it is even more important not to burden the cleansed body with such questionable substances. The body is apt to react violently to their use and, even if it does not, the organism is subjected to the necessity for breaking down these substances, attempting to utilize whatever nutrients are present, and eliminating the excesses and waste products. The resultant stress and expenditure of energy is often more than can possibly be obtained from the pills.

It is true that, following a fast, there is an urgent, an imperative, need for proteins, minerals, and vitamins—not from pills or powders, but from whole natural fruits and vegetables and from raw, unsalted nuts and seeds. These contain all of the nutrients, in the best and most available form.

After the fast, one should learn to live in such a manner that the low tolerance level will be retained. Toleration of toxins interferes with the normal functioning of the body, inevitably leading to the first

stage of toxemia (enervation, lack of sufficient nerve energy) which is followed later by disease and death of tissues.

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > 6. Take It Easy!

## **6. Take It Easy!**

After returning home, one should not be in too much of a hurry to return to the full schedule of responsibilities and obligations. One should resume activities gradually; get plenty of rest and eat carefully, so as not to dissipate the benefits that have been achieved. The investment in health will not pay off if one does not "follow through."

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > 7. Fasting Does Not Make The Body Disease-Proof

## **7. Fasting Does Not Make The Body Disease-Proof**

The fast is but the first step in combating disease and must be followed by correct living. People who have suffered from chronic degenerative ailments should never make the mistake of trying to keep one foot on each side of the fence that divides the conventional and Hygienic rationale. After the prolonged fast, they should never regress to conventional eating patterns or return to the "prevention syndrome" of health management, lest their problems return.

It is difficult to imagine that anyone who has experienced the wonders of a prolonged fast could ever be persuaded to turn away from Natural Hygiene, for such a mistake could be serious, perhaps disastrous.

The principles of Natural Hygiene and the use of fasting are grounded in the study of cause and effect. Remove the causes of ill health by Hygienic living and the effect will be improved health. Remove the accumulated effects of previous irrational living (by fasting), and the body will tend toward healing and rejuvenation.

Fasting does not insure the body against disease. It is true that some symptoms and manifestations of disease disappear during the fast and do not return. But there are some diseases that have a tendency to return swiftly after the fast if the faster returns to the old habits which caused the disease. Much depends on the type, extent, and gravity of the degeneration, and on the strength and vitality of the individual.

During the first weeks or months—perhaps even during the first year or two after a prolonged fast, the mode of living and eating may be critical in the preservation of the health improvement which has been achieved.

## **8. Compounding The Benefits Of The Fast**

If Hygienic living is maintained after the fast, the benefits of the fasting period will continue to be noted for weeks, months, and even years after the termination of the fast.

The relationship between fasting and nutrition must be recognized. Recovery from a pathology can often be accomplished through fasting, but permanence of the recovery is dependent on the subsequent mode of living, particularly the food program.

Some people accept the fast as a more or less dramatic and drastic necessity—but think of it as a cure-all, after which all their problems will disappear.

Subsequent to my 29-day fast in 1967, my unrealistic expectations gave rise to a feeling of disappointment. I expected to experience perfect health immediately. Actually, it was not until a year had elapsed that I realized the full consequences of my fast, and knew the fullness of the miracle that had occurred in my body.

Years later—in 1979—I had a similar experience. I had been bothered with a slight but persistent pain in my side for almost two years. Although I had been fasting thirty-six hours twice monthly, and had taken several three- and four-day fasts, the slight pain persisted.

Then I decided on a longer fast but, because of time limitations and prior commitments, I broke the fast after nine days. (You see, I am subject to the same pressures and human failings that I may deplore in others. Ideally, I should have fasted longer, possibly even to completion.)

In any event, the small pain persisted during the fast, and subsequent to the fast. I was busy, and decided to ignore it for the time being, and really forgot about it most of the time.

About six months later, I suddenly turned to Lou (my dear husband) and exclaimed, "It just dawned on me—I don't have that pain in my side any more—and I don't know when it stopped!" It has never returned.

## **9. New Habits Must Be Formed**

Fasting is a means of promoting health by eliminating the disease-causing conditions—by cleansing the body of accumulated toxins and allowing it to heal itself.

Perverved appetites can be normalized by fasting, but new habits must be formed to supersede and overcome any pressures to return to the appetites that produced the disease.

The period immediately following the fast is the best time to form and maintain the habits that will give one the feeling of having been born again.

Dr. Shelton says, "The true remedy for all impairments of health is a complete correction of the way of life. When enervating habits are discontinued, the sick will begin to get well, and, once having recovered, to stay well unless the enervating habits are returned to."

The prolonged fast for the elimination of toxemia is but the initial preparation for a program for the restoration of good health. Health evolves out of correct living. The fast begins the reversal of the processes of disease, so that the self-healing powers of the organism may initiate the health-restoration

processes.

But the most important factor in the progress toward optimal health is making the necessary changes in the habits of living. Unless the change to correct living is made after the fast, there can be no permanent good health.

Never forget—Natural Hygiene is a way of life. Fasting is not a modality to be employed to correct uncomfortable symptoms, after which one may return to the mode of life that produced the disease.

Hygienic living, especially if complemented by the use of regular, short fasting periods, as an instrument of health maintenance is the best assurance and insurance for good health and longer life.

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > 10. Questions & Answers

## 10. Questions & Answers

### **How soon after a prolonged fast could one plan to return to working full time?**

There is no way to give an accurate estimate of the time required. The factors involved are the gravity of the pathology, the length of the fast, the physical condition of the individual, the rate of return to normal strength and weight, and the type of work. If the faster was obese, and fasting for weight loss primarily, that person would very likely recuperate very quickly. If the weight of the faster is quite low when the fast is terminated, it will obviously be necessary to allow considerably more time for recuperation. I would say that, after a 21- to 30-day fast, one should usually expect to need at least a month, and possibly two months or more, to be able to return to a full and demanding program. I have, however, known people who recovered full strength and vitality in less time. Essentially, it depends on the individual and other circumstances of the fasting situation, and is really more or less unpredictable.

### **How long after breaking a fast should one stay at the fasting retreat?**

Again, as for the answer to the previous question, there is not one general answer applicable to all cases. However, it is best to arrange to stay long enough to become established in the new eating program, and beyond the stage where one "feels hungry all the time." After a 21- to 30-day fast, two weeks of eating should be considered the minimum before leaving the retreat; if there are any unresolved problems, it would be best to stay longer.

### **Exactly what do you mean by fasting to completion, or the return of true hunger, and how many days of fasting do you estimate that would require?**

Fasting to completion, or the return of true or natural hunger, is considered to be a point at which the body has relieved itself of most of its toxic load, and has almost exhausted those reserves which can be utilized for salvaging nutritive materials. It is considered to be close to the point at which fasting ceases and starvation begins. The signs that this point has been reached are obvious to the fasting supervisor, and most of these signs are mentioned in the lesson. It is impossible to estimate how long this will take. I have known people who fasted 30, 40, and 45 days, with no signs of the return of true hunger. I even knew one very obese lady who fasted 92 days (after which she was still obese—she had lost 87 pounds) and there were still no signs of natural hunger at the termination of her fast. On the other hand, some of these signs have been reported at the end of 20 to 30 days of fasting, and even more at the

end of 40 to 45 days. The length of time it would take is essentially unpredictable, but it usually only occurs in the very long fast.

### **What is meant by nitrogenous equilibrium?**

Nitrogen is the chief ingredient of protein, and every 6.25 grams of protein contains one gram of nitrogen. A protein deficiency, or negative nitrogen balance (where protein is being broken down more rapidly than it is being built) exists:

1. When the diet is not supplying adequate protein for maintenance and repair.
2. When the diet is deficient in some essential amino acid.
3. When the body is receiving an insufficient supply of carbohydrates and fats, and must deaminate necessary protein to supply energy needs.
4. When the body has lost its ability to properly digest, assimilate, or synthesize proteins.

Nitrogenous equilibrium (nitrogen balance) is normally maintained by a healthy organism which is receiving 25 to 50 grams of protein daily. A Hygienic diet, consisting mostly of raw fruits and vegetables, plus two to four ounces (maximum) of raw nuts and seeds taken 2-3 times a week, will adequately meet the protein needs of the body, and will result in nitrogenous equilibrium, unless a related serious pathology exists. In this case, a fast may be necessary to reestablish the ability of the body to properly digest, assimilate, and synthesize proteins. If alternate sources of concentrated protein are used in addition to nuts and seeds (sprouts, cheese, legumes, grains), the amounts of nuts and seeds used should be reduced. People on all-raw-food diets usually require fewer concentrated proteins. Obviously during a fast, protein is not being supplied by the diet, and minimum protein needs are met through the process of autolysis, as the body disintegrates the least important tissues, and salvages nutrients to meet its needs. So long as the fast is not continued after reserves are depleted, nitrogen balance will not be affected. It is true that, subsequent to the fast, the body will have lost much of its store of protein, which must be gradually replaced in the weeks and months following the fast. As quoted in the lesson, Chittenden says that, although, after the fast, the body is greatly in need of replenishment of its protein stores, it can replace them only slowly, even though the person eats abundantly of protein food.

### **What do you mean when you refer to the pathogenic debris of cooked food?**

A study by Swiss scientist, Paul Kouchakoff, M.D. (in the 1940s), revealed that leukocytosis is caused by a preponderance of cooked food in the diet. Leukocytosis—the augmentation of the number of white corpuscles, and the alteration of the correlation of the percentage between them—was formerly considered to be a normal physiological phenomenon, since it seemed to occur after every consumption of food.

An excessive number of white corpuscles in the blood (leukocytosis) also occurs in response to inflammation, the presence of excessive numbers of bacteria, and is, in reality, a *pathological* phenomenon

The white corpuscles are the defense organisms of the blood that prevent intoxication of the blood by bacteria, cooked food, or other toxic materials.

Kouchakoff found that pressure cooked foods produced greater leukocytosis than other types of cooking; and that wine, vinegar, and white sugar produced even more. Prepared or processed meats (cooked, smoked, salted) brought on the most violent reaction, equivalent to the leukocytosis count in poisoning.

"After the consumption of fresh raw foodstuff, produced by nature, our blood formula does not change in any lapse of time, nor in consequence of any combination." (Viktoras Kulvinskis, *Survival Into the 21st Century*, p. 316.)

When the diet is comprised of more than 20% of food that has been altered by high temperatures or other complicated treatments, leukocytosis is the result. Most people can tolerate a diet of 80% raw food, with 20% of conservatively cooked food. The largely raw food diet will offset the adverse effect of a small amount of cooked food, so as not to cause leukocytosis.

Kouchakoff's conclusions were reached after more than three hundred experiments on ten individuals of different ages and sex.

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > Article #3: Breaking the Fast By Dr. Herbert M. Shelton

### **Article #1: Breaking the Fast By Dr. Herbert M. Shelton**

An important fact that needs emphasis is that fasting is a very much more complicated process than is commonly supposed, even by its advocates. There is much more involved in the process than merely going without food. There is an art of fasting, but, if this art is to be properly executed, it must be based on the science of fasting. Its uses seem, at times, to be almost unlimited, its inconveniences are not great, its dangers are few and rarely seen, but for the most satisfactory results, it must be conducted by one skilled in its application. It is too vital and too important to be carried out indifferently. It is not a process that should be left to the guidance of those who have but limited knowledge of its proper conduct and who have had no experience in conducting fasts. Breaking the fast is one of the most important elements of the fast.

It is possible to break a fast on any food that is available—bread, flesh, eggs, nuts, etc.—providing a few simple precautions are observed. Animals follow none of our routines in breaking their fasts. They eat whatever is at hand and do not regularly stint themselves at their first meal. From this, it may be thought that we are unduly cautious, but I do not think so. Not only are there differences between what the animal does and what the average patient tends to do, if turned loose, but there seems to be great differences in digestive power, in favor of the animal. There is also the possibility that the animal would preserve more of the benefits of the fast if it broke the fast more carefully.

We do not employ the foods previously mentioned in breaking a fast for the reason that better means of breaking the fast are available to us. At the end of a long fast, digestive secretions are not abundant and small meals or small amounts of food are advisable. The amount of food fed to the patient is increased as secretion becomes more abundant. When this rule is observed, there is little difficulty in breaking a fast and no danger in doing so.

The proper conduct of the fast is vitally important. There are really very few practitioners of any school who know how to conduct a fast or how to properly break one. A naturopath in New York City broke the fasts of a mother and a daughter, who had been fasting sixteen and thirteen days respectively, on chocolate candy. The gastric and intestinal acidity resulting from this caused great distress throughout their bodies. I was called in one these cases, and it required four to five days of fasting to get them back into a comfortable condition. This method of breaking a fast is nothing short of criminal.

A friend of my wife describes to me how she fasted seventeen days under the direction of a chiropractor

in California and worked hard during the fast. She worked for the chiropractor and he would not permit her to leave from work while fasting. He broke her fast with toast and acid fruit. This woman immediately developed a case of malnutritional edema. This is one of the few cases of this kind I have ever known to follow a fast.

This case should thoroughly emphasize the necessity of placing one's self under the care of a competent and experienced person, if one is to take a long fast. A chiropractor who knows nothing of either fasting or dietetics, and few of them know anything of either of these, and who experiments with patients in this manner, cannot be too strongly condemned. If chiropractors want to practice Hygienic methods, let them qualify themselves for this by proper training. This goes also for osteopaths and medical men. I would not attempt a surgical operation without first qualifying myself for the work, and I am certain that no chiropractor, osteopath, or medical man should attempt a long fast, or attempt to employ any other Hygienic method without first equipping himself for the work. Chiropractors who go to school and learn to punch spines and then, finding spine punching to be inefficacious, attempt to prescribe diet, etc., after reading a book or two on these methods, are in the same position as would be the medical man who attempted to "adjust" spines after reading a book on chiropractic. He is really dishonest and untrustworthy.

Dr. Wm. F. Harvard records the following cases: "A young man of twenty-four years of age who had suffered from chronic constipation and indigestion, fasted 27 days after reading an article in a popular health publication. On the 28th day he ate a meal of beefsteak, potatoes, bread, and butter and coffee. He was seized with violent vomiting spells and could not tolerate even a teaspoonful of water on the stomach. When called on the case, I discovered an intense soreness of the entire abdomen and every indication of acute gastritis." "A young man about 30 who had fasted on his own initiative for 42 days attempted to break the fast on coarse bread with the result that vomiting occurred and the stomach became so irritable that nothing could be retained. There was marked emaciation and extreme weakness and every indication for immediate nourishment."

An Associated Press dispatch dated August 28, 1929, recounts the death of Chris Solbert, 40-year-old art model, following a 31-day fast, which he broke by "consuming several sandwiches." The sandwiches, a later report said, contained beef. Ignorance and lack of self-control killed this man. The dispatch tells us that "his fast (of 31 days) had reduced him from 160 to 85 pounds," or an average loss of more than two pounds a day. This loss I believe to be impossible. The average losses for a fast of such length vary between 25 and 36 pounds.

"Professor" Arnold Ehret tells of seeing two cases killed by injudicious breaking of the fast. He says: "A onesided meat-eater suffering from diabetes broke his fast which lasted about a week by eating dates and died from the effects. A man of over 60 years of age fasted 28 days (too long); his first meal of vegetarian foods consisting mainly of boiled potatoes."

Ignoring the absurd explanation for these deaths, given by the "professor," we would say that the diabetic patient threw too much sugar (from the dates) into his body and died as a result of hyperglycemia. He probably passed out in a diabetic coma. He explains that the second patient fasted too long for a man of his age, and that an "operation showed that the potatoes were kept in contracted intestines by thick, sticky mucus so strong that a piece had to be cut off and the patient died shortly after the operation." "Professor" Ehret was so fond of mucus he could never see anything else. This fast was badly broken but the patient, in all likelihood, would have lived had he not been operated on. The fast was not too long for a man of that age. "Professor" Ehret really knew but little of either fasting or dietetics.

These cases help to influence many against fasting and yet they are the results of the worst type of ignorance and inexperience. Who but an ignoramus would feed a diabetic case a meal of dates after a week of fasting? Surely fasting cannot be blamed for this result. Before we talk of the "evils" and "dangers" of fasting, let us be sure that these really belong to fasting and not to something else.

Sinclair says: "I know another man who broke his fast on a hamburger steak, and this is also not to be

recommended." I had one patient break a fast of over 20 days by eating a pound-and-a-half of nuts the first day. Although no harm, not even slight discomfort, came from it in this particular case, this method of breaking a fast is certainly not to be recommended generally.

In some cases of fasting where efforts are made to feed the patient towards the latter end of a prolonged fast, but before hunger has returned, there has been noted a failure of the stomach to function. Dr. Dewey mentions such cases, who were induced by friends or physicians to eat, and who were absolutely unable to digest food but vomited everything eaten. Fasting was resumed and continued until the return of natural hunger, with the result that digestion proceeded nicely.

Reprinted from *The Hygienic System—Volume 3*

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > Article #2: Fasting Not a Cure By Dr. Herbert M. Shelton

## **Article #2: Fasting Not a Cure By Dr. Herbert M. Shelton**

In 1959, a veterinarian who was employing fasting in the care of his animal patients and had done experimental work with fasting, wrote me: "In running down Dr. Pochedly's bibliography on fasting, I find that an extensive amount of fasting was done by medical men and osteopaths as recent as 1930, with excellent results being obtained in many symptom-complexes—the greatest factor in the subsequent failure of the laudation of fasting seems to lie in the fact that no one knew how to direct the patient to live so that he would not sink back into his symptom-complexes. Nothing is said about removal of causes."

The doctor here puts his finger on a vital point. The after-care of the faster is every bit as important as the proper conduct of the fast itself. All of the benefit derived from a lengthy fast may be wiped out in a few weeks or in a few months by improper living following the fast. The assumption, so commonly made, that fasting is a cure and that all one has to do is to fast and he will be well, has resulted in many failures. It is important to understand that health is rebuilt by a total way of life of which fasting is but a part.

It is also important to know that fasting does not make one proof against the effects of wrong ways of life. If one is addicted to smoking or drinking alcoholic liquors, the fast will not enable him to continue these practices with impunity. Only "*cures*" hold out to man the hope of recovery from the effects of causes while these causes are still in operation. Only "*immunizers*" hold out to man the hope of being made cause-proof. "*Cures*" and "*immunizers*" are *thaumaturgic* processes—they belong to voodooism, not to science.

The doctor's statement underscores the importance of proper supervision of the fast and the subsequent program of living which is vitally essential to full results. It also, by inference, stresses the importance of education in correct ways of living. Not merely should one eat correctly following a fast, but one's whole pattern of life should be brought into harmony with natural law. If this is not done, the results of the fast will not be lasting.

It is important, in this connection, to emphasize the fact that, if one is to maintain the gain made during a fast, one must rigidly adhere to a Hygienic plan of living, at least, sufficiently long to consolidate the gains made. Were it possible to wipe out the effects of a lifetime of wrong living by a few days to a few weeks of fasting and completely restore health by this means alone, it would mean that the wrong living was not so bad after all. It would mean that one may drink, smoke, overeat, overindulge, and neglect himself to his heart's content, and then take a fast and wipe the slate clean. Only cure-mongers would

hold out such a promise and false hope to the suffering.

Altogether too many members of the *cure*-oriented schools of so-called healing have dabbled in fasting. It is a matter in which they are untrained and for which they are unqualified. No amount of training in drug therapeutics, in manipulations, in spinal adjusting, in electro-therapy or in surgery can possibly qualify a man to conduct fasts. Fasting is a subject that must be studied and in which one should have guided experience, before attempting to conduct a fast.

[Home](#) > [Lesson 48 - How To Break A Fast; After The Fast](#) > Article #1: Breaking a Fast by Dr. Herbert M. Shelton

### **Article #3: Breaking a Fast by Dr. Herbert M. Shelton**

In his personal account of his fast of thirty-one days which he underwent in the Carnegie Institute in 1913, Prof. Levanzin says: "I have put under experiment nearly all the systems for breaking a fast. The *how* is as dangerous as the *when*. To mine I have added the experience of my wife, my daughters and of many of my friends. After a mature and long meditated study of physiological principles tested by practical methods, I think that I have arrived at the right solution. I had the intention of giving my system a thorough test during the breaking of this last fast, but I could not do it as I had to follow unwillingly somebody else's inflexible will."

The professor states his case when he states that the *how* of breaking a fast is as dangerous as the *when*. Breaking a fast is very easily and simply done and there need be no danger associated with the process. A few simple rules need to be observed in all cases and the need for these is in proportion to the length of the fast and the general state of the faster. Many fasters have harmed themselves, and in a few cases have ended their lives by eating too much or by eating unsuitable foods and food mixtures.

Prof. Levanzin says, "Dr. Goodall, who was in charge of me during the fast from the medical point of view, insisted on having my fast broken on 'clam broth' and 'beef tea!!!' And because I told him that these would kill me he and Dr. Benedict gave up and put all the responsibility on my shoulders. I took it and broke the fast successfully without any inconvenience although it was afterward spoiled at the hospital."

It is not likely that clam broth and beef tea would have killed the professor, although, from where I sit, neither of these two slops is suitable human food under any circumstance of life. For death to have resulted from breaking his fast on clam broth and beef tea, he would have had to consume them in inordinately large quantities. Without proper supervision in breaking a fast, the individual may eat too much or too often or he may eat unsuitable food and bring harm upon himself.

In considering the inappropriateness of some foods and food mixtures for breaking a fast Upton Sinclair wrote, "Since leaving the Macfadden Healthatorium, I have at various times had occasion to fast, and have tried other articles of food upon which to break the fast. While I was down in Alabama, I took a twelve-day fast, and at the end I was tempted by a delicious large Japanese persimmon, which had been eyeing me from the pantry shelf during the whole twelve days. I ate that persimmon—and I mention that it was thoroughly ripe; in spite of which fact it doubled me up with the most alarming cramp—and in consequence I do not recommend persimmons for fasters. I know a friend who had a similar experience from the juice of an orange; but he was a man with whom acid fruit has always disagreed. I know another man who broke his fast on Hamburg steak; and this also is not recommended. I have another friend who fasted a week and broke the fast with rice and soft boiled eggs, and this friend also got no benefit to speak of from the experience, although the foods agreed with her perfectly and she had no temptation to overeat. This is about what I should have expected, as my own experience has led me to

believe that the worst food that people eat are those highly concentrated pasty things which are deficient in natural salts and contain no waste to keep the intestines active. A person can eat food like eggs and rice for weeks and never have a movement of the bowels. I know it, because I have done it; and I can give myself as durable a headache by that means as other men can get with a hamper of champagne."

Macfadden broke fasts with fruit juices and followed this with the milk diet. This diet was very popular as the milk was taken every half hour during the day and fully satisfied the keen sense of hunger that follows a fast and provided for a rapid gain in weight. Macfadden says he has seen gains of three pounds a day and records he has seen instances of gain of twenty-five pounds in a week following a fast by means of the milk diet. My own observations of and experiences with the milk diet coincide with his. I have seen gains of three pounds a day and ten pounds a week. I saw one man gain twenty pounds in one week. The milk diet was not discontinued because of a loss of popularity, but because the dairy industry made it increasingly difficult to obtain raw milk, and because it was found impossible to obtain the same desirable results with pasteurized milk.

The weight gained on the milk diet was in large measure due to overloading the body with fluid, as shown by the puffiness of the face, feet, and ankles and the speed with which it was lost when the milk diet was discontinued. The milk diet overworked the heart, the digestive system, and the kidneys, and increased blood pressure. It was not an ideal diet with which to follow a fast.

In my recent book, *Fasting for Renewal of Life*, I have emphasized the fact that fasting animals in wild nature break their fast upon whatever food the season and locality afford. They do not have the advantage of electric machines to express the juice from foods, but eat their food whole. Man may do the same. A fast may be broken on any wholesome food that is available. Greater caution is required with some foods than with others. The chief requirement is simplicity and a small quantity at a time. If fed in great quantity or too often, the most suitable food may give trouble. Individual articles of food that may give no trouble in the great majority of cases, may give trouble in an occasional case. I have never broken a fast with persimmons but I doubt that most people would suffer cramps, as described by Sinclair, were we to break their fast with persimmons. The case is different with pineapple. This fruit frequently takes the skin off the lips and tongue of the eater. While I have never broken a fast with pineapple, I have fed pineapple two and three days after breaking a fast, and find it frequently causes distress in the stomach in addition to peeling the lips and tongue. Such experiences bring up the question: Is pineapple a suitable food for man?

Prof. Levanzin says: "I break my fast on acids and carbohydrates followed immediately by protein food. The ease and rapidity with which tissues are rebuilt, without any untoward accidents, is really astounding."

He gives no details about his technique of breaking a fast and we cannot do more than suggest that perhaps his plan of breaking fasts was not ideal. If he mixed the acids and carbohydrates together or if he mixed the carbohydrates and protein, his post-fasting feeding program could have been greatly improved.

It has been contended by many, the fast should be broken upon the food craved by the faster. The faster is likely to crave the foods he was in the habit of eating before he underwent the fast or he may crave some item of food that he sees or sees a picture of while the fast is in progression. The craving may be psychologically rather than physiologically conditioned. It will be better to break the fast upon some simple food the wholesomeness of which is undoubted, such as an orange, or a tomato, or a peach, or a plum, or a small piece of watermelon.

## Article #4: When to Break the Fast

Early Hygienists said: when your tongue is clean, your rest peaceful, your skin clear, your eyes bright, there is no more pain, and you are very sharply hungry, you may select from the store of wholesome articles of food described in works of Hygiene, that which pleases you and eat with moderation. That is sound advice, but hardly detailed enough. The usual indications for breaking the fast (these help to determine the dividing line between fasting and starving) areas follows:

1. *Hunger* invariably returns.
2. The *breath*, which during all or most of the fast has been offensive, becomes sweet and clean.
3. The *tongue* becomes clean. The thick coating which remained on it throughout most of the fast vanishes.
4. The *temperature*, which may have been subnormal or above normal, returns to exactly normal, where it remains.
5. The *pulse* becomes normal in time and rhythm.
6. The *skin* reactions and other reactions become normal.
7. The *bad taste* in the mouth ceases.
8. *Salivary secretion* becomes normal.
9. The *eyes* become bright and eye sight improves.
10. The *excreta* loses its odor. The *urine* becomes light.

Besides the usual signs that it is time to break the fast, Prof. Levanzin lists a feeling of cheer and elation as a manifestation that the time has arrived for the termination of the fast. I cannot do better than quote Carrington's description of the feelings of the patient at this state. He says (*Vitality, Fasting and Nutrition*, p. 544), "A sudden and complete rejuvenation; a feeling of lightness, and good health steals over the patient in an irresistible wave, bringing contentment and a general feeling of well-being, and of the possession of a superabundance of animal spirits." Circulation improves, as is seen by the resumption of the normal pinkness under the fingernails. The increased rapidity with which the blood flows back into the skin when this has been forced out by pressure, is another indication of the rejuvenating effect of the finished fast."

The primary indication that the fast is to be broken is the return of hunger; all the other indications which I have enumerated are secondary. Often one or more of these secondary signs are absent when hunger returns, but one should not refrain from breaking the fast when there is an unmistakable demand for food, merely because the tongue, for example, is not clean. Inasmuch as all the signs do not invariably appear in each case, do not hesitate to break the fast when hunger returns.

[Home](#) > [Lesson 49 - The Organic Garden; Avoiding Commercially Produced Foods - Why?](#) > 1. Organic Gardening Is The Counter-Part Of Natural Hygiene

### 1. Organic Gardening Is The Counter-Part Of Natural Hygiene

Organic gardening, or planned growing without poisons, is the best way to produce flavorful food that will build healthy bodies. The procedures in organic gardening utilize the concept of the cycle of plant life in a virgin forest—birth, life, death, and return to the earth for decomposition and enrichment of the soil for the ensuing cycles. The preservation of the ecological system in your garden can be a big factor in preserving the eco system in your own body.

Organic gardening is the counterpart of Natural Hygiene—it is a system of growing healthy plants in cooperation with nature by utilizing only naturally occurring materials for improving the soil and fertilizing, and for combating insect or disease problems.

They both, organic gardening and Natural Hygiene, work the same way—if you provide the body with the best possible conditions for optimal health, you can avoid disease; if you provide your garden with the best possible conditions for growing healthy plants, if you work *with* nature instead of *against* it, if you *maintain* the balance of nature instead of *destroying* it, you can anticipate success. You will harvest a bountiful crop of food of excellent flavor, high nutritional value, and free of residues of chemical

fertilizers and poison sprays.

In the 1980s there is increasing interest in organic gardening because of its impact in the solution of environmental problems, and the growing awareness of the important role of organic food in the improvement of health.

[Home](#) > [Lesson 49 - The Organic Garden; Avoiding Commercially Produced Foods - Why?](#) > 2. What Exactly Is Organically-Grown Food?

## 2. What Exactly Is Organically-Grown Food?

Organic gardening has been traditional in European countries for many years, but, by the 1940s, farmers and gardeners in the United States had gotten farther and farther away from earlier growing methods, and chemicalization had begun to prevail. About that time, a significant organic-gardening movement was pioneered by J. I. Rodale, of Emmaus, Pennsylvania, founder of *Organic Gardening and Farming magazine*. Since then, many of his followers have produced fruits and vegetables of extraordinary quality.

J.I. Rodale worked on many public projects in opposition to pesticides and drug cartels, made a significant contribution to agricultural sciences, and helped establish "organic" as a household word.

The Rodale organization formulated a scientifically-sound definition of organically-grown food which is today accepted as bona fide by most leaders of the natural, organic movement, and by officials of the U.S. Department of Agriculture.

The following is the official definition: *Organically-grown food is food grown without pesticides; grown without artificial fertilizers; grown in soil whose humus content is increased with applications of natural mineral fertilizers; and has not been treated with preservatives, hormones, antibiotics, etc.*

[Home](#) > [Lesson 49 - The Organic Garden; Avoiding Commercially Produced Foods - Why?](#) > 3. Soil Analysis

## 3. Soil Analysis

Many advocates of organic gardening will tell you that the first step is to have your soil analyzed to determine what elements are missing, and to determine its pH—that is, the degree of its acidity (sourness) or alkalinity (sweetness), because the pH has a relationship to the ability of the soil to support the growth of various plants. (pH is a chemical symbol denoting the concentration of hydrogen ions per liter.) You might decide to bypass this step.

On a scale of 0 to 14, pH values from 0 to 7 indicate acidity; values from 7 to 14 indicate alkalinity; pH 7, the value of pure water, is regarded as neutral. Soil in most low rainfall areas tend to be alkaline; soil in high rainfall areas are usually somewhat acid.

The continual addition of organic material to the soil generally provides the necessary elements for plant nutrition, and tends to stabilize the pH, with the result that vegetables with a variety of pH preferences can be grown together successfully. Most vegetables prefer soils that are neutral or slightly acid (pH 6.5). See chart of pH preferences in supplementary section of this lesson.

A slightly-acid soil is best for availability of nutrients. If the soil is too acid, calcium, magnesium, and phosphorus levels decrease, and manganese and aluminum may be too available, even toxic. The pH of a very acid soil can be raised by adding dolomite lime. In alkaline soils over pH 7.5, iron, copper, manganese, zinc, and phosphates may become less available. Organic matter is the best remedy for such very alkaline soils. Humus or organic matter tends to neutralize either overly-acid or overly-alkaline soils.

For simple pH readings, you can test your soil with a kit. If serious problems persist, professional soil analysis can point out sources of trouble. Most gardeners discover what will grow well in their soil by observation and trial-and-error.

[Home](#) > [Lesson 49 - The Organic Garden: Avoiding Commercially Produced Foods - Why?](#) > 4. Basic Steps To Establish A Successful Garden

#### **4. Basic Steps To Establish A Successful Garden**

There are many ways to go about producing a living soil, containing all the known and unknown minerals, and billions of microorganisms. If the soil in your garden has been misused by pollution with chemical fertilizers, pesticides and herbicides, or by depletion of its organic matter without recycling anything back into the soil, it will take more heroic measures, and a longer period of time, to bring the system back into balance.

A virgin soil may have also been damaged. It may have been "robbed" of its topsoil by builders and graders, or decreased in value by mixture with the subsoil. The surface soil, or topsoil, usually is the top eight to fourteen inches of the soil, and is darker and more fertile than the subsoil. In any event, a new garden hasn't had time to build up a deep friable (readily crumbled) soil full of nutrients and microorganisms. But you can still have a successful first year crop, if you follow a few simple steps. There are three basic steps for growing plants successfully:

1. Produce a living soil, light and crumbly, granular, water retentive, and containing all the substances necessary to plant life. It must contain organic matter, living organisms, the proper soil "atmosphere," moisture, and nutrients for growth of plants and microorganisms. There are three basic soil types: clay, sand, and loam. Clay takes in water slowly, drainage is very low, and aeration is limited. Plant roots have a difficult time penetrating clay soil. Gypsum and lime can improve aeration and drainage of clay soils. Organic matter will improve air circulation (compost, ground bark, sawdust, leaf mold, peat moss).

Sandy soils have the opposite problem—it lets in plenty of oxygen, and roots pass through easily. It has good drainage—too good!—the water and water soluble nutrients pass through too quickly. Add a finely-textured, spongy, organic material that will hold water and nutrients. Peat moss is such a material, and it has the advantage of slow decomposition, but it contains practically no nutrients. (Also, large amounts of peat moss may increase the acidity of the soil.) Compost breaks down faster, but supplies nutrients to the soil. Wood products and hulls are not much benefit to sandy soils. If you obtain clay to add to your sandy soil, this will help to create a balance.

The addition of these and other organic materials will eventually change the sandy soil into good garden loam, containing a balance of different sizes of particles, and a good supply of humus (a dark sticky substance created by decomposition of organic materials). This loam will be loaded with valuable nutrients and capable of producing healthy vigorous food plants.

Loam is the ideal soil. Few gardeners are blessed with a naturally-loamy soil, but it can be gradually built almost anywhere.

2. Keep the soil in your vegetable garden and under your fruit trees covered at all times with approximately six inches of organic mulch. The mulch for gardens and vines should range in height from three to six inches, fruit trees from six to nine inches.
3. Supply adequate moisture. A deep watering once or twice a week is far preferable to a light watering every day. Light rain showers of less than one-half inch should not interrupt the regular water schedule. Shallow water encourages the roots to turn upwards towards the moisture and may kill the plants. Deep watering, encourages a deep, strong root system. Do your watering in the early morning or late evening. Do not overwater your garden or trees—it is not necessary to water every day.

Because it is often high in sodium, artificially-softened water should not be used. The leaf-tips of many plants turn brown from artificially-fluoridated water, or from water with a high natural fluorine content.

## 4.1 Getting Started

Clean out the grass and weeds in your garden area and do some digging to loosen the earth. Dig down about a foot or so, but avoid turning under the topsoil. You will probably have to do little or no digging in subsequent years, if you grow organically, with a permanent mulch, because the soil will be easy to work.

Sprinkle some organic compost thinly over the soil (or dig it in, if you wish), and cover with six inches of mulch. This should be done at least three or four weeks before the first planting. Tuck all your table scraps (preferably raw) in between the layers of mulch; this is called sheet composting. Start to do this immediately, and then continue this sheet composting after the garden is planted and growing. (Banana refuse is a particularly rich source of nutrients, and loved by earthworms.) These table scraps never become garbage. There is no odor or animal nuisance, if the scraps are hidden in the mulch—not too deep, say, an inch or two. As time passes, the organic matter in the soil will convert to humus, and biological activity of bacteria and earthworms will develop under the mulch.

[Home](#) > [Lesson 49 - The Organic Garden; Avoiding Commercially Produced Foods - Why?](#) > 5. Gardening The Magic Way—With Mulch, Compost, Sea Weed Spray

## 5. Gardening The Magic Way—With Mulch, Compost, Sea Weed Spray

### 5.1 Mulch

You can mulch with anything that will decay, if it doesn't contain toxic or poisonous substances. Some materials are better than others. A very good mulch material, easy to obtain (at no cost) is grass clippings, your own or your neighbors'. If possible, spread them out to dry, before using them to mulch your garden. If you do use green clippings, don't apply them directly to the soil, as this can rob the soil of nitrogen. Spread green clippings in a thin layer on top of previously-applied "cured" mulch; this will allow them to dry. If applied in a thick layer, they may mat down, become slimy, build up heat, and develop odors.

Piled up or bagged green grass clippings will get hot, but, when spread on the ground, they don't even get hot enough to hurt earthworms. But don't put fresh or green mulch up against tender young plants, as enough heat may build up to scald the plant. Of course, trees should never be mulched right up to the

trunks, even if the mulch is "cured"—at least ten inches from the trunk for citrus trees and several inches for other fruit trees.

You should also use all the leaves you can get. There are many other mulch materials: hay, straw, wood chips, sawdust, cottonseed hulls, peanut shells, corn cobs, seaweed and sea grasses, ashes, and some others—almost anything that will decompose without being too messy.

Dried grass clippings mixed with leaves are often the most practical. This is clean and easy to handle, and enhances the appearance of your garden and trees. If you have oak leaves in your mulch, it will repel slugs, snails, cutworms, and June bug grubs. Alfalfa grass is an excellent mulch—it contains a valuable amount of nitrogen.

Maintaining a six-inch organic mulch at all times conserves moisture, and helps to produce the conditions for building a living soil and a top-quality garden. The mulch also creates conditions which discourage nematodes (microscopic worms which produce root knot, causing deterioration or death of plants). A permanent mulch also controls erosion, regulates soil temperature, and eliminates the necessity for spading, raking, cultivation, and weeding.

Cover crops will be unnecessary, you will need less compost, and fewer insect controls. The mulch encourages earthworms, which help to aerate the soil and enrich it with their castings. The soil will never get hard or muddy, the vegetables will be clean and pleasant to harvest.

Mulch makes "sheet composting" easy and practical—because you can tuck your table scraps in between the layers of mulch and there will be no eyesores, odors or other nuisance. It is not necessary to remove the mulch in the spring "so the ground will warm up" or in the winter when frost threatens. Because some weeds grow in cool weather, keep the ground well mulched all winter.

Mulch is indeed the gardener's "magic carpet," relieving him of many tedious tasks, and aborting a large percentage of incipient problems. If you make no other changes in your gardening methods, at least don't fail to take advantage of this easy "green thumb" idea.

## **5.2 Compost**

Organic compost is a fertilizing mixture of various organic substances, which have been mingled and decomposed. Many people build their own compost in piles, pits or bins, and there are various methods of doing this, but it does take some space, time and work, and you and your neighbors might also have to put up with some odors and flies, although there are ways to avoid both by careful planning and attention. If there are many citrus peels in the compost, there will be noticeably pleasant odor. Don't ever put in wet garbage without a covering layer.

One of the simplest method of building a compost pile is described in *Down to Earth Vegetable Gardening Down South* by Bullard and Cheek. Start with an eight-inch layer of grass, leaves and kitchen wastes (mingled or in any order); next a two inch layer of manure or other nitrogen source. Cover with a one-inch layer of earth, and sprinkle generously with water. Continue this three-layer series, building to a maximum height of five feet. If shredded materials are used, the compost will be ready in a few weeks, and no turning of the pile will be necessary. Occasional light sprinklings of dolomite lime will add nutrients (magnesium and calcium) and create a better balance, Greensand is another excellent soil conditioner. It comes from deposits laid down in what was once the ocean, and contains potash, magnesium, iron, silica and other trace minerals. Some other organic-fertilizing materials are rock potash, straw, alfalfa, hay, tobacco stems, peanut shells, and soybean meal. It is much better to include these fertilizing materials in a balanced organic compost than to try to use them individually.

## **5.3 Seaweed**

Seaweed is a rich source of nutrients. If you can get seaweed or sea grass, use them. Some people prefer to wash the seaweed before using, or weather for three months, to reduce or eliminate the salt transfer,

but these processes may also leach out other valuable nutrients.

If seaweed is not available, you can obtain a nutritional seaweed spray. One of these products is called "Maxicrop Liquid Seaweed (Kelp Extract)." It is a soil activator and conditioner, and its use results in a crop of higher yield and better quality. It helps to produce stronger, healthier plants with greater resistance to insects, disease, and adverse climatic conditions. The effect is cumulative and the soil improves with each application.

[Home](#) > [Lesson 49 - The Organic Garden: Avoiding Commercially Produced Foods - Why?](#) > 6. Soil Requirements For A Successful Organic Garden

## 6. Soil Requirements For A Successful Organic Garden

### 6.1 Nitrogen

A balanced organic compost should contain nitrogen, phosphorus, and potash (potassium). As a rule, calcium, sulfur and magnesium, as well as trace elements like zinc, boron, manganese, molybdenum, copper, and chlorine (and many other trace minerals, known and unknown) will be available in your soil for plant nutrition, if you are constantly adding a variety of organic materials to your soil.

Nitrogen is important in the production of protein; leafy, green vegetables, especially, need adequate supplies of nitrogen. Too little nitrogen will be evidenced by pale green leaves, progressing to yellowing and dropping of older leaves, and stunting of growth. Too much nitrogen will produce an excess of greenery and little or no fruiting, and the plants may be spindly and weak, and susceptible to disease.

Nitrogen is supplied by blood meal, castor pomace, soybean meal, cottonseed meal, fish meal, or feathers, or bone meal, or straw, alfalfa hay, or manure. If you use bloodmeal or manure, use it very sparingly.

Nitrogen is also supplied to the soil by growing legumes, which capture nitrogen from the air, enriching the soil in which they grown, as well as adjoining areas. (The air is almost 80% nitrogen.) Earthworms will also help supply nitrogen to the soil. See the article "Nitrogen Fixation" in this lesson.

[Planet Natural](#) carries "Alaska Fish Emulsion," an excellent source of nitrogen. *Do not* add concentrated nitrogen to plants when fruits are ripening. To encourage ripening, add either a balanced compost, or phosphorus or potash.

### 6.2 Alfalfa: The Best Source of Nitrogen (Plus Growth Stimulation)

In 1975, Dr. Stanley K. Ries, a horticulturist at Michigan State University, found that alfalfa treated plots produced increases far above what the nitrogen in the alfalfa could account for.

In the laboratory, they isolated the active agent—triacontanol, a fatty acid alcohol which occurs naturally in the plant's leaves. Triacntanol is not a fertilizer, but a growth stimulating substance.

The Rodale Organic Gardening Research Center tested the use of "greenchop" alfalfa in extremely small counts. Both Ries and the Rodale Center reported (*The Best Gardening Ideas for the '80s*) that the less alfalfa they applied, the better the yield—but, with no alfalfa, they got the lowest yield. The amount used which provided the best yield works out to about one cup of fresh chopped alfalfa for 100 square feet of garden. Simply spread it over the plot, work it in, and plant your vegetable seeds. Use mulch as usual.

The Rodale book says that the methods and rates of application are still in the experimental stage.

The main advantage of alfalfa is as a nitrogen-fixing legume. Fresh-cut alfalfa contains more nitrogen than any manure. Use alfalfa in the garden as a soil-enricher to be rotated through the garden, or as a patch to produce a high-nitrogen material for mulch.

### **6.3 Phosphorus**

Phosphorus is necessary to the production of plant sugars. The symptoms of phosphorus deficiency are similar to those of nitrogen deficiency, but the leaves may be dull green with purple tints. Some phosphorus sources are rock phosphate, bone meal, granite dust, natural limestone, gypsum, and fish scraps.

### **6.4 Potassium (Potash)**

Potassium (potash) is essential to the life processes of plants. It is helpful in hastening development and maturity. Symptoms of potassium deficiency are slow growth and leaves with mottled yellow tips and edges, and scorched-appearing edges on older leaves. Seaweed or seaweed spray provides generous amounts of potassium. Some other potash sources are wood ashes, granite dust, potash rock, citrus rinds, kelp, greensand, and bone meal.

### **6.5 Calcium**

Enough calcium will usually be present in the soil, but bone meal will supply some additional calcium especially needed for grapes, celery, and sometimes tomatoes.

### **6.6 Sulfur**

Like nitrogen, sulfur is a protein provider, and will usually be present in adequate amounts in the organic garden.

### **6.7 Magnesium**

Magnesium is a vital nutrient, important in the leaves of living plants. It is necessary for the process of photo-synthesis—through which plants manufacture their own food and fuel—utilizing energy from the sun, carbon dioxide from the air, and water and nutrients from the soil. Usually there is enough magnesium present in the soil of an organic garden. However, occasionally, an acid-loving plant will indicate a deficiency, evidenced by yellowing leaves, which may be corrected by using dolomitic limestone or raw phosphate rock.

### **6.8 Feed the Soil Which Feeds the Plant**

See the list of compost materials, with percentages of nutrients, in the supplementary section of this lesson.

Organic compost—and the various nutrients of organic origin which may be added to the soil—do not overwhelm plants with a tremendous amount of one particular element, as can happen with chemicals. The chemicals attempt to feed the *plant*, whereas the organic fertilizers feed the *soil* which nourishes the plants.

This more natural way produces the best food, and makes it unnecessary to be preoccupied with exact ratios of various elements, such as the 6-6-6 chemical fertilizers (6% nitrogen, 6% phosphorus, 6% potash). Generally speaking, these nutrients from organic sources should be added in approximately equal amounts, but be particularly careful not to use too much nitrogen from animal sources (such as manure, blood meal, or dried blood). Your soil will make the best use of the organic fertilizers for the

nutrition of your plants.

Sand Mueller, instructor in horticulture at Triton College in suburban Chicago, says that seven years ago he was operating a conventional greenhouse in New Mexico. He visited greenhouses all over the Southwest, all of which used agricultural chemicals. All of them had insect problems, and all of them used powerful poisons.

Mueller had read claims by organic gardeners to the effect that their healthy plants had little or no insect problems. He says, "I believed these assertions were preposterous, as did every horticulturist I knew."

But he eventually decided to try the compost idea, and his insect and disease problems rapidly began to disappear. After he started to compost, he learned the law of survival of the fittest in the plant kingdom.

Mueller tells how, in 1936, a British agricultural scientist, Sir Albert Howard, grew half a field of alfalfa with artificial fertilizer and half with compost. His oxen devoured the compost-grown alfalfa first. Given a choice, animals will always select the organic food.

After building up the health of the oxen with the organic feeding, Howard deliberately exposed them to the hoof and mouth disease, but none of the oxen became ill. Dr. William Albrecht, professor of soil science at the University of Missouri, corroborated Howard's findings.

In 1976, Mueller offered his flock of chickens the choice of commercial feed or grains he had grown in composted soil. He says, "With a cacophony of cackling and scratching, my hens asserted the truth of Howard's claim."

Mueller says, "The horticulture establishment has only one response to compost and that is ridicule. It is the response of ignorance. I do not believe that there exists anyone in the field of agriculture who has tried organic agriculture who now advocates chemical agriculture."

[Home](#) > [Lesson 49 - The Organic Garden; Avoiding Commercially Produced Foods - Why?](#) > 7. Approximate Amounts Of Compost, Mulch And Water

## **7. Approximate Amounts Of Compost, Mulch And Water**

Before planting vegetable seeds, put in fifteen pounds of compost per one-hundred feet of row. Even if the compost is put in immediately before planting, the compost will not burn the seeds as does chemical fertilizer. If possible, however, put the compost in at least a week or two beforehand.

After the seeds are planted, soak the ground every day until the seeds sprout, then every other day. Put in one inch of mulch when the seeds begin to sprout. Add more mulch as they grown taller. Put more compost between and around the plants when they begin to bloom, and again when fruiting.

When setting *seedlings* or *plants*, put in the compost, then cover the ground with one inch of mulch, and then set in the plants. Soak the ground every day for two or three days, preferably in the late afternoon, then every other day.

## 8. Planting Your Garden

Select the sunniest spot for your garden, but near a source of adequate water. Morning exposure to full sunlight is the most beneficial. If part of your garden is shaded, that is the place to put leaf crops. Avoid low wet areas.

A good size for a family garden is 200 to 600 square feet in area, but smaller ones will also produce a lot of vegetables if planted with small seeds such as lettuce and carrots. Plant seeds in rows that are six inches wide, with six inches between the rows. This pattern will result in a harvest of approximately four times as much as you would get from single rows. Leave a walk space of about 16 inches between each 18-inch unit.

Map the layout of your garden. To minimize shading, arrange low-growing vegetables along one side of the garden, medium-tall plants in the middle, and tall ones on the other side. Design your garden with companion planting and crop rotation in mind. (Details later.)

Plan to grow the vegetables you like to eat, and be sure to get seeds that are suitable for planting in your area. Don't use seeds that have been treated or dipped in chemical solution. Look for the varieties that have been developed for resistance to disease.

Don't use last year's seeds—they seldom come up as well as fresh seeds. In most cases, it is not a good idea to save your own seeds. They often do not grow true to type, and the amount of labor spent collecting, drying, and storing these seeds will probably make them twice as expensive as buying new seeds.

If you soak your seeds for a few hours, or overnight, or even twenty-four hours, before planting, germination will be easier and more certain. Soak in plain lukewarm water, or, better yet, in a 1% solution of seaweed spray. If you sometimes don't take the time to soak your seeds, try using the 1% seaweed solution as a seed dip.

Don't sow the seeds too thickly, and be sure to cover them with soil to a depth of about four times their diameter. Firm the soil by patting or walking on it. Then stay off the planting area. The seeds must be kept moist until the seedlings appear.

For a steady supply of vegetables, make successive plantings, or plant several varieties of the same vegetables but with different maturity dates.

You might decide to use some started plants, especially if you are a little late in starting your garden. When thinning and transplanting plants, handle them carefully, allow as much earth as possible to cling to their roots, and give them a good watering after transplanting. Do your transplanting after the sun has gone down.

Be sure to plan for as many fruit trees as possible, limited only by the available space and your ability to care for them. If you harvest more fruit than you can use, you will have a good marketable crop, especially when organically grown. Offer your surplus fruit (at a fair price) to your friends, neighbors, health food stores, and supermarkets. If you have a large crop, it could even be advertised with good results.

Give your fruit trees what they need, but don't feel you must be doing something for them constantly. Mostly, you should leave them "intelligently alone"—the same advice as Hygienists give for the care of the human body. The trees can work out most of their problems by themselves, if you do not complicate the situation by the use of poisons.

Don't overlook grapes and berries! Be sure to select the proper varieties for your area. And don't forget to include some nut trees.

More details about fruit and nut trees will be given in the next lesson: "The Pluses in Orchard: How to Get Started."

[Home](#) > [Lesson 49 - The Organic Garden: Avoiding Commercially Produced Foods - Why?](#) > 9. Insects: Friends And Foes

## 9. Insects: Friends And Foes

An organic gardener does not try to destroy the entire insect population in his garden. Not only is this the epitome of futility, but it is neither necessary nor advisable. There will be some insect damage, no matter what is done. Ignore the early signs, and don't feel you must do something about it, unless your crop is threatened. Eventually, you will learn to recognize your friends in the insect population: the ladybug, the praying mantis, beneficial beetles, flies, wasps, lacewing flies, fireflies, dragonflies, and spiders. They are predator insects whose food is the scavenger insects, preventing them from increasing to dangerous levels.

The first step to insect control is, of course, the building of a living soil, containing all the substances necessary to produce healthy, disease-resistant and insect-resistant plants. Next, be sure to provide adequate moisture for your garden. Your permanent mulch will help to conserve the moisture, and will create conditions which discourage many insect pests.

### 9.1 Companion Planting

An important step in insect control is companion planting. Wild plants almost always grow in mixed communities, where each type of plant contributes to the support of others growing nearby.

Even when plant species are mixed with no planned basis, insect problems are reduced. The more of the same plant you have growing together, the more insects are attracted, as they get the clear signals from the larger planting. Interplanting and aromatic herbs confuse their sensory apparatus.

Companion plants influence, complement or supplement each other, and grow in harmony together. Mixed plantings tend to create and maintain a natural balance between beneficial and destructive organisms.

Members of the same plant families, which are subject to the same pests and diseases, should be separated—like tomatoes and potatoes; cucumbers, melons, and squash; and cabbage, broccoli, and cauliflower.

Legumes capture nitrogen from the air, feed it to adjoining plants, and enrich the soil in which they grow. Beans, corn, and cucumbers like to grow together. Or plant beans with eggplant and rosemary. Soybeans, especially, deter chinch bugs and Japanese beetles. Plant peas, leaf lettuce, strawberries and cucumbers with carrots, radishes and chives; turnips with peas; onions and garlic with most vegetables except legumes. Beets and onions are compatible; so are leeks and celery. Plant cabbage, broccoli or Brussels sprouts with beets, kohlrabi, and cucumbers.

Tomatoes are good with onions, parsley, carrots, and marigolds, but do not like kohlrabi. Bush beans like beets and potatoes. The strong scent of marigold seems to act as a deterrent to insects throughout the garden, and their roots secrete a substance that kills nematodes. Be sure to plant some around tomatoes and beans.

Some plants need a lot of light and are excellent companions to those that need partial shade. Lettuce likes cabbage and beets, but can also be put under tall plants that provide some shade. Deep rooting

plants bring up the minerals from the subsoil, enriching the top layer, and they aerate the soil for plants with a shallow root system.

Plant nasturtiums in your vegetable garden near broccoli, cabbage, cauliflower, and cucumbers, and between fruit trees, to repel aphids. Chives and onions will also repel aphids. Garlic will prevent bacteria damage and damage from peach borers. Garlic and onions will deter most pests, but don't plant any near beans or peas. Most strong smelling plants are useful in repelling pests.

There is a long list of companion plants, vegetable preferences and insect repellent plants and herbs. You will find such a list in the article section.

Companion planting, and the use of insect repellent plants, will not prevent insect damage, but will reduce it considerably; it will be a profitable investment.

## 9.2 Crop Rotation

Crop rotation can help to prevent and control perpetuation of many problems, such as depletion of particular trace elements in specific areas of your garden, and perpetuating insect problems or diseases that can survive in the soil from one year to the next. Implementation of the available information about crop rotation can contribute to a successful garden.

If you are maintaining a permanent mulch, crop rotation may not be absolutely necessary, but it is still an excellent idea, and it does not entail a great deal of extra trouble to relocate plantings each year. If you would rather not bother rotating, but will maintain a permanent mulch and keep building the soil, try doing without the crop rotation; you may find it will not be necessary in your garden. However, I believe rotation to be a good precautionary measure at least in the second and third years of your garden, even if you decide to abandon this procedure after your soil has been built up.

For those who do want to take advantage of crop rotation, here are some suggestions:

Avoid growing the same vegetables (or crops of the same family) in the same location more than once every three years. Plants subject to the same problems should not follow each other in the same bed. Don't use successive plantings of lettuce, cabbage, or celery in the same soil. They are subject to the same fungus attacks.

Cucurbits (cucumbers, squashes, pumpkins, gourds, melons) should not be grown near any other member of the gourd family, and there should be a lapse of at least three years between plantings of any of these in a specific area in order to reduce the risk of the fungus disease anthracnose.

Heavy feeders should be followed by light feeders. Leaf crops consume large amounts of nitrogen from the soil, root crops use up the potash, so don't plant turnips after carrots, nor lettuce in the same bed, year after year.

Legumes (peas, beans) are excellent to precede or follow potatoes, but not to precede sweet potatoes. Members of the cabbage family, or lettuce, are excellent choices to follow legumes.

A rotation chart for vegetables to follow legumes (*Organic Gardening*, March 1974) suggested cabbage, broccoli, Brussels sprouts, mustard greens, lettuce, and parsley, as first choices; corn, leeks, shallots, radishes, turnips, onions, and Irish potatoes as second choices; tomatoes, eggplant, peppers, and okra as third choices; and suggested that the following vegetables not be used behind legumes: carrots, beets, sweet potatoes, cantaloupes, pumpkins, cucumbers, squash. The varieties of legumes upon which the experiments were based were: Crowder, Purple Hull, Silver Skin, and English Peas; and Bush Lima, Pole Lima, Bunch Snap, and Pole Snap Beans.

Leaf vegetables or cucumbers that have had lots of compost may precede or follow potatoes. Potatoes should never follow tomatoes or vice versa.

Don't plant peppers where cucumbers have grown within the last year.

Be sure to grow a variety of vegetables and don't be afraid to experiment. Failures with some will be offset by successes with others, just as in any other method of gardening.

Crop rotation is so little trouble that it seems a shame to overlook this method of increasing the potential of your garden.

### **9.3 Biological and Logical Insect Controls**

Start out with the idea that some insect controls will be necessary, especially in the initial period before your soil has been built up. You may want to try biological controls like praying mantis egg cases, Trichodrama wasp eggs, or imported lady bugs—success with these varies. The problem with these imported insects is that they may soon migrate to another location that suits them better.

Another very successful biological insect control is the presence of birds, toads, lizards, etc. Provide trees, bird-houses, bird baths and bird feeders, and shallow pans of water on the ground for the toads and lizards, who will also appreciate shrubbery and mulch.

Sanitation and good housekeeping in your garden will prevent a lot of problems. Carefully remove and destroy all diseased plants and wash your hands thoroughly before handling other plants. Remove all dropped fruit and garden trash. Watchfulness and handpicking is an old-fashioned, but effective, method of controlling some insects.

Cardboard collars around the stems of your plants help to ward off cutworms. Aluminum foil collars around young seedlings keep off fleas, reflect the rays of the sun and give the plant more warmth.

Other effective insect controls are wood ashes, black pepper, lime, or rock phosphate dust mixed with water, and a homemade spray or drench of garlic, onions, hot red peppers (and a little soap to make it stick). A good recipe is one cup hot peppers, three whole garlic bulbs, three medium onions. Blend with one pint water (or a little more). Strain, add enough water to make one gallon, and apply to both under and on top of leaves. It is easier to use this in a sprinkling can, as it may clog the sprayer, but you may have to use a spray for the undersides of the leaves.

Beer (or a solution of baking yeast, or any other ferment) in a shallow dish attracts slugs—and drowns them. Wet areas are their hiding places.

Rye flour or clay, dusted on plants when the morning dew is fresh, will trap soft-bodied insects and the sunshine will bake them.

Decayed insect sprays or drenches are useful. Insects are repelled by the scent of dead bodies of their own species.

A spray or drench of soapsuds is effective against aphids, mites, and plant lice. Rinse with clear water within a few minutes.

Some experiments made in 1979 at the University of California, showed that soap solutions can be used effectively to combat a number of plant-feeding insects. Among the soaps which were included in the experiments were "Shaklee's Basic H" and "Fels Naphtha Laundry Bar" soap. The least damage to plants was achieved when the liquid formulations were used at 1% to 2% (7 teaspoons to 5 tablespoons to the gallon); and bar soaps or powders at 1.5 to 2 ounces per gallon of water. More concentrated solutions provided more effective control, but also increased the potential for plant damage. Of course, soap solutions do not have any residual activity, and repeated applications are necessary. However, even when applied only once or twice a year, beneficial results are achieved. It is best to use soap, *not detergent*. Three tablespoons of "Ivory Flakes" to a gallon of tepid water is safe and effective.

### **9.4 Insecticides, Repellents, Fungicides**

If you must resort to insecticides for your garden and trees, some which will not poison your food are available. A dormant oil spray, obtainable at nurseries, in a 3% miscible solution, may be used during the

dormant period on certain fruit trees, and also, in a weaker dilution, as a spring and summer spray, to control certain insects. This is an effective control for many sucking and chewing insects, including aphids, thrips, scale insects, mites, red spiders, white flies, and mealy bugs. The eggs of codling moths, oriental fruit moths, leaf rollers, and cankerworms are also destroyed.

A one-time application of "Milky Disease Spore Powder" (called "milky" because it causes an abnormal white coloring in the insect) will prevent damage by Japanese beetles on your property and your neighbor's, since it spreads underground. It is supposed to be harmless to everything except the Japanese beetle grub.

An excellent multipurpose control of caterpillars and chewing insects is the product "Thuricide" (another spore-type pest disease, called *Bacillus Thuringiensis*) which is extremely efficient for use in the vegetable garden on vines and fruit trees, and kills more than 100 species of harmful insects. The instructions say this product may be used up to the day of harvest. To be effective, the leaves of the plants must be ingested by the insects, as "Thuricide" is a stomach poison for them. "Dipel" is another manufacturer's name for the same formulation.

Most diseases exhibit specific symptoms, so it is not too difficult to differentiate from insect damage. It is not difficult to identify insect damage caused by sucking insects like aphids or thrips, and chewing insects like caterpillars.

Sucking insects cause leaves to curl and become spotted, or they may turn yellowish, stippled white, or gray. These insects and their brownish eggs or excrement can often be seen on the underside of the leaves.

Aphids cause curling or cupped leaves, or round or conical protrusions. Thrips leave a black deposit of tiny specks, or whitish streaks.

Caterpillars, grasshoppers, weevils, and flea beetles are some of the chewing insects which eat the leaves. Flea beetles make tiny round perforations; weevils produce angular holes, beetle larvae (grubs) skeletonize leaves, eating everything but the veins.

Red spider mites, which are so tiny they are practically invisible, deposit tiny tents of fine cobwebs on terminal leaves, and can be found (with a magnifying glass) on the underside of the leaves—under a strong magnifying glass in a good light, you may see tiny specks about the size of fine meal.

Cyclamen mites cause deformed leaves; leaf miners produce blotches or tunnels. Round or coned protrusions can be caused by either midges or gall wasps.

Both nematodes and gall wasps can cause the partial or total collapse of a plant.

A useful product suitable for organic gardeners is "Neutral Copper" by [Southern AG](#), a fungicide which, when used according to directions, will control many plant diseases, without poisoning your food. I have not found it necessary to use the neutral copper spray on any of our vegetables, but have used it on avocado trees, citrus trees, and some grape vines. It should be used, sparingly, at the first signs of disease. It may also be used as a precautionary measure on avocados, mangos, citrus, and some varieties of grape vines (not necessary for muscadine grapes) to avoid infection from scab and antracnose and some other diseases. These plants are subject to such diseases (which may be averted through the occasional use of a fungicide).

The best time to apply neutral copper as a preventive of disease is just before new growth starts in the spring, and when two-thirds of the petals have fallen. It is not advisable to use a neutral copper spray in the fall on your citrus or other fruit, as its use at that time of the year may prevent the fruit from sweetening. If disease problems occur at this time of the year, just prune out the infected leaves and dead wood.

Some of the specific symptoms of plant diseases are:

1. Brown circular spots on fruit, or dieback of twigs and loss of leaves about a foot from the tips

(fungus).

2. Rust—leaves look like they are covered with rusty powder (fungus).
3. Fire blight—drying up of blossoms, blossom stems, or fruit (bacterium *Erwinia amylovora*).
4. Dark brown spots in leaves with small pinpoint-like objects (fungus).
5. Grayish-white leaf with brown margin (mildew).
6. Discoloration of stem at ground level—slick and slimy (damping off).
7. Leaves that show watersoaked areas within leaf (bacterial infection).
8. Circular spots with definite color around the outside of the infected spot (fungus).
9. Leaf gall (azaleas)—thick growth causing excessive cells (fungus).
10. Mold on plants may be due to location in a cool, damp, sunless area.

One should use a little soap (not detergent) as a spreader-sticker for all sprays, so they will adhere to the plants, instead of running off. The products referred to above usually need to be used only rarely and sparingly. It doesn't take long to learn to recognize insect damage or disease and to evaluate the necessity for controls. Most healthy plants, however, rarely need controls.

Tobacco stem mulch will repel aphids, flea beetles, and thrips, but should be used cautiously, if at all. Some plants, like tomatoes, don't like tobacco; and the nicotine content of such a mulch may kill beneficial earthworms, insects, and organisms. Tobacco could also carry disease to some of your plants, especially potatoes, eggplants, tomatoes, or peppers. I don't use tobacco stem mulch.

Black leaf— a nicotine spray—may be used as an emergency treatment for aphids, thrips, or other small insects, but use it only if you must. It is subject to many of the objections listed above for tobacco mulch. I don't use "Black Leaf."

In extreme cases for emergency use only for a severe infestation, it might be necessary to use one of the insecticides made from rotenone, pyrethrum, ryania, or quassia, which are plant extractives. "Sevin" (available at nurseries and garden supply stores) is such an insecticide, and will control the bean leaf roller and the bean skeletonizer, and various other insects, but you ought to first try "Thuricide" for these problems.

The plant extractive insecticides, such as "Sevin," should be discontinued completely as soon as moderate control has been attained. They are not completely harmless, but there will be no residue if you wait fourteen days before harvesting. I have never resorted to these insecticides, and, of course, would never even consider the use of a more dangerous insecticides like "Malathion."

If you would like acceleration in your recognition of insect damage, diseases, deficiencies, and problems in your garden, and want to study the subject, see pages 590-91 (deficiencies) and pages 340-51 (diseases) in Rodale's *How to Grow Vegetables and Fruits by the Organic Method* and *The Bug Book* by John and Helen Philbrick.

Gil Whitton, Pinellas County (Florida) Agriculture, recommends Cynthia Westcott's *Plant Disease Handbook*, which is available in libraries as a reference book. As Mr. Whitton says (St. Petersburg, *Florida Independent*, 3/6/75), "No one book or person can have all the answers."

If you have problems with "raiders" (rabbits or other small animals), this can be very frustrating. The best solution is a fence to keep them out. See the article in this lesson, "Containing Inhibits Raiders."

## 10. The Case Against Commercially-Grown Foods

### 10.1 Hazards of Chemical Fertilizers, Pesticides, Fungicides, Herbicides, Fumigants, etc.

The snowballing evidence against chemical pesticides culminated in Rachel Carson's landmark book, *Silent Spring*, led to the ban in the United States of D.D.T., and restrictions on the use of other poisons on food crops.

On December 25, 1975, an article appeared in the *St. Petersburg (Florida) Independent*, entitled "Pesticides Can Kill People, Too." Georgia Tasker, of the Knight Newspapers, wrote about the experience of Joan Cole with the insecticide "Sevin" (which is not supposed to be as bad as such insecticides as "Malathion"). She dusted a big tomato ring with "Sevin" on a dry day. A couple of days later, she decided to discard the plants altogether, and jerked them out on a windy day. The next day she felt as though she were having a nervous breakdown. She couldn't get up, she couldn't think straight. Ms. Cole said, "I had really panicky feelings. My whole body sort of went into limbo or something." The next day, when she felt a little better, she racked her brain, and then it dawned on her that she must have inhaled "all that damned stuff."

The article continues, "Dr. John Davies, a pesticide expert at the University of Miami Medical School, has been analyzing the tissue of a Fort Walton Beach (Florida) woman who recently died. Initial autopsy tests indicate Mrs. R.J. Clark may have become fatally ill after inhaling too much nemagon, a pesticide used to control nematodes. "Helen Lund, another Miami gardener, has given up using pesticides altogether. She was caring for the plants of vacationing friends and mixed some Malathion, used it, and decided to take the leftover mixture home. She drove home with it in the back seat of her car. By the time she reached her house, she was dizzy and sick to her stomach. She said, 'I got to thinking this is going to kill the birds—and me.'

"So while the Environmental Protection Agency continues to crack down on dangerous pesticides, banning in July of this year chlordane and heptachlor except for very limited use, the possibilities of severe sickness and death are always present when using any pesticide."

The World Health Organization has released figures disclosing almost 500,000 *reported* cases of pesticide poisoning in 1981. For every reported case, how many others do not report or even recognize the relationship of their ailments to pesticide exposure or ingestion?

As Hygienists, we are concerned about the hazards of ingesting chemical residues in our drinking water or in our food. How many thousands of workers are also exposed to the dangers involved in handling pesticides, or in growing or handling the crops?

### 10.2 The "Benefits"?

The chemical cartels maintain that the risk is small compared to the benefits achieved. *What benefits?*

Modern insecticides are nonselective, killing or injuring beneficial insects and animals, and persisting in the environment, upsetting the ecological balance. *All* chemical pesticides upset the eco balance so significantly that crop yields eventually diminish.

The National Audubon Society says, "Between 80 and 90 percent of pesticides used in homes and gardens do no good at all. More often, they do harm. These chemicals are a hazard to wildlife, pets, and humans. None of them are totally safe. And they often cause more problems than they solve."

### 10.3 Chemical Fertilizers vs. Organic Methods

Chemical fertilizers may initially increase the abundance of crops, but the eventual result of failing to replace the exhausted elements of the soil is depletion.

Tests made in the early 1960s on the Rodale crops in Emmaus, Pennsylvania, indicated a decided superiority in nutritional value of organically-grown food over the commercial varieties. Crops were grown side by side, half organically and half commercially (using chemical fertilizers and insecticides). Otherwise, the conditions were identical.

The crops were then tested to see how they compared in nutritional value. Six nutrients were measured, and the reports indicate the superiority in nutritional value of organically-grown food. The following comparisons between the organically-grown and the commercially-cultivated wheat and oats gives the higher percentages of these six nutrients in the organically-grown crops:

Nutrients	Organically-Grown Oats	Organically-Grown Wheat
Protein	28% higher	16% higher
Vitamin B1	92% higher	108% higher
Vitamin B2	171% higher	131% higher
Niacin	100% higher	63% higher
Calcium	25% higher	29% higher
Phosphorus	3% higher	1% higher

But the best proof is when we taste and enjoy the better flavor of the food.

An article in the *Palm Beach (Florida) Post*, July 29, 1974, by Bryce Nelson, Chief of the Middle Western Bureau of the *Los Angeles Times* in Chicago, tells about organic farmers who increased their yields, increased the quality of their produce, and improved their own health and the health of their stock. Most of them sold their products at regular prices on the open market. The organic farmers said their fertilizer cost was lower, they had to do less work to get as high or higher yields than chemical farmers, and they were happier.

In a 1976 study for the National Science Foundation, Dr. Barry Commoner determined that organic farming methods produce foods more economically, and of higher quality. The study, made with organic farmers in five states, showed that foods cost \$16 an acre less to produce. (The claim is usually made that organic farming is more trouble and more expensive than chemical farming.)

More recently, Purdue University Agronomist Jerry Mannering reported evidence of the importance of organic matter to plants. The correct chemical and physical composition, of the soil, and the soil energy, can be maintained only by conservation and replacement of organic matter. Only organic matter can create and maintain in the water-holding and nutrient-holding capacity of soils.

### 10.4 No Differences? Use Supplements?

Numerous representatives of vested interests maintain that there is no difference in the .nutrient quality of safety between chemical food production and food produced organically.

Other vested interests maintain (and even exaggerate) the food deficiencies created by chemical food production, and offer a solution—vitamin and mineral supplements.

Hygienists must face these issues squarely, and determine how to resolve the contentions resulting from these claims.

Synthetic fertilizers may initially help produce *larger* fruits and vegetables, but they are often lacking in taste and lower in nutritional value. Vitamins and minerals, proteins and enzymes in foods that are produced organically have repeatedly been shown to be superior, qualitatively and quantitatively. And, inexorably, when the soil is depleted, exhausted by the use of chemical agriculture, what then?

In 1900, wheat in Kansas contained about 18% protein. Today Montana wheat (grown in virgin soil) also contains 18% protein. But Kansas wheat today contains only 11% protein, because the virgin soil is depleted and the farmers are using chemical fertilizers.

The late John Tobe, in *The Provoker*, November-December 1976, said, "The food processors and chemical corporations have arranged for various professors of great universities to go on the stump and make statements that there is no special value in organically-grown foods. Here I would like to tell you about some research that was conducted at the Massachusetts Institute of Technology. Many foods grown in the United States were compared with their counterparts grown in Mexico, Central America and Latin America. It was found that many of the foods grown in the U.S. are lower in nutritional value than the same foods grown in Mexico, Central America, and Latin America, where chemical farming has not been established." The caption of the article is "Sometimes It Pays To Be Blind."

Many people acknowledge that commercially-grown food is deficient in nutritional value, and it is well known that organically-grown food is more abundant in trace elements, which are necessary to life. One example is the deficiency of copper, a necessary trace element, which is destroyed by chemicalization. Too many people try to restore these deficiencies by augmenting their diets with food supplements (pills, powders, liquids) in the vain hope of supplying missing nutrients. It can't be done! In the lesson about food supplements, you learned that these products are useless, and even damaging.

[Home](#) > [Lesson 49 - The Organic Garden; Avoiding Commercially Produced Foods - Why?](#) >

## 11. Four Methods

There are four methods of gardening:

1. Natural—This method does not poison the soil, but does deplete it, especially of nitrogen, and its productivity gradually decreases.
2. Chemical—This method increases the production the first and second years, at the cost of flavor and nutritional value (lower protein content and higher carbohydrate content) and destruction to the environment. The plants must rely on artificial chemicals to stimulate their growth, and, as time goes on, more and more chemicals are needed and problems increase. Insects mutate and develop resistant strains, the microorganisms and earthworms in the soil are killed by the chemicals, and the farmer or gardener develops neurological diseases from inhaling the sprays or absorption through the skin.
3. Organic—This method replenishes the soil, and is the method described and advocated in this lesson, to produce a better-quality crop, without poisoning the food, the environment, or the gardener. The organic gardener uses only organic materials (organized living matter).
4. Biodynamic—The term "biodynamic" refers to "working with the energies which create and maintain life." This method of agriculture uses organic methods, including compost, but also uses

herbal preparations to spray the plants and trees. The basic ingredient of the biodynamic spray is a specially-prepared colloidal clay compound. The spray flows into all small cracks and crevices of the plant and forms a protective film, to help in healing minor lesions, but does not interfere with the respiration of the plant. The spray also contains very low percentages of such insecticides as ryania, rotenone, pyrethrum, and quassia, far below customary concentrations, because the spray is not intended as an eradicator. These insecticides are plant extractives, but are not completely harmless, as indicated previously. The recommendation is to wait fourteen days after spraying before harvesting. The biodynamic spray is also available without the insecticides. The biodynamic spray is also said to enable the plants to derive certain nutrients from the atmosphere. This system was originally started by Rudolph Steiner, and developed by Dr. E. E. Pfeiffer. The biodynamic method is more sophisticated, more complicated, and more work than the organic methods described in this lesson. We tried biodynamic methods in Indiana, but found them more difficult and no more productive than simpler organic methods.

An amusing illustration of the difference between natural and organic methods is a story told by Dr. Alec Burton at American Natural Hygiene Society Conventions about a gentleman who came to Yorkshire, England, and took over an extremely dilapidated property. He did a great deal of work on this property, renovating it and getting it into a beautiful condition, and, eventually, people came from miles around to admire and appreciate his garden. One day the local priest came to see it, and said, "What a beautiful garden you have!" The man said, "Yes, it's been hard work, and I've done it all by myself." "No," said the priest, "with the help of the Lord." The man said, "All right—with the help of the Lord, but you should have seen it when he was doing it by himself."

There is quite a bit of information available for the organic gardener who wants to learn how to get maximum results. *How to Grow Vegetables and Fruits by the Organic Method* by J. I. Rodale and staff (mentioned previously) is an excellent comprehensive reference book, listing practically all varieties of food plants, with detailed planting instructions for each.

For those who want a few simple rules for growing food with a minimum of time and energy, moderate success can be anticipated by simply using organic methods, instead of chemicals; and mulching instead of cultivating and weeding.

[Home](#) > [Lesson 49 - The Organic Garden; Avoiding Commercially Produced Foods - Why?](#) > 12. No Space For A Garden?

## **12. No Space For A Garden?**

If you live in an apartment or condominium and don't have space for a regular garden, you can still grow some of your own food on your porch or patio. You can use boxes, barrels, or make a wall garden. Small plants like lettuce, squash, cucumbers, or strawberries need boxes only four to six inches high. Tomatoes, peppers, cauliflower, and cabbage need more space for their roots, and these boxes should be at least ten or twelve inches high.

Vine branching plants (cucumbers, squash, melons) can be trained to spread over the patio floor (concrete or whatever). They require little box space. Grapevines can be planted along a building wall or fence.

You can build a wall garden anywhere you have a little space. Annie Silvan describes a wall garden and how to build it. She says that it is like a large block or wall of soil with plants growing out of all sides. "You will need four one-by-six boards two feet long, four one-by-six boards five feet long and at least 14 two-by-two poles four feet long." Make two bottomless boxes out of the one-by-sixes—a frame for

the top and one for the bottom. Nail the two-by-twos to these frames, one foot apart. It will look something like a cage with vertical bars. Leave the bottom and the top open, but line all sides (inside) with open mesh wire and then black plastic. Secure the mesh with wire. Place the wall in its permanent position, fill with soil, and water from the top so the soil will settle. Use tomatoes and root vegetables at the top; lettuce, strawberries, cabbage, cauliflower, or any leafy greens on the sides. Make little holes in the plastic to insert the plants. Water all around and on top.

Patio tomatoes (in pots) are easy to grow. Leaf structure is easy to grow. I once grew some in several large flower pots. You can grow sunflower seeds to the green leaf stage in flats by pressing unhulled seeds into the soil and keeping them moist. They are ready for harvesting in a week. Buckwheat, adzuki beans, lentils, mung beans, or any other seeds or beans can be grown the same way, and will produce a product which is superior nutritionally to seeds sprouted with only water, since they will have the benefit of the earth, sun and outside air.
